Regulatory Status

Several cryosurgical devices have been cleared by the U.S. Food and Drug Administration. For example, in 1996, the Endocare™ Cryocare System (Endocare) was cleared for marketing through the 510(k) process for “use in general surgery, dermatology, neurology, thoracic surgery, ENT [ears, nose, and throat], gynecology, oncology, proctology and urology for the ablation of tissue, including liver metastases, skin lesions, warts, and removal of prostate tissue.” U.S. Food and Drug Administration product code: GEH.

Rationale

Background

Liver Metastases

Hepatic tumors can be due to primary liver cancer or metastases to the liver from nonhepatic primary tumors. Primary liver cancer can arise from hepatocellular tissue (hepatocellular carcinoma) or intrahepatic biliary ducts (cholangiocarcinoma). Multiple tumors metastasize to the liver, but there is particular interest in the treatment of hepatic metastases from colorectal cancer (CRC) given the propensity of CRC to metastasize to the liver and its high prevalence. Liver metastases from neuroendocrine tumors present a unique clinical situation. Neuroendocrine cells produce and secrete a variety of regulatory hormones (or neuropeptides), which include neurotransmitters and growth factors. Overproduction of the specific neuropeptides by cancerous cells causes various symptoms, depending on the hormone produced.

Treatment

Treatment of liver metastases is undertaken to reduce endocrine-related symptoms, in addition to prolonging survival and reducing symptoms related to the hepatic mass.

Surgical resection with tumor-free margins and liver transplantation are the primary treatments available that have curative potential. Many hepatic tumors are unresectable at diagnosis, due either to their anatomic location, size, the number of lesions, or underlying liver reserve. Local therapy for hepatic metastasis is indicated only when there is no extrahepatic disease, which rarely occurs for patients with primary cancers other than CRC or certain neuroendocrine malignancies. For liver metastases from CRC, postsurgical adjuvant chemotherapy has been reported to decrease recurrence rates and prolong time to recurrence. Combined systemic and hepatic arterial chemotherapy may increase disease-free intervals for patients with hepatic metastases from CRC, but apparently is not beneficial for those with unresectable hepatocellular carcinoma.

Various locoregional therapies for unresectable liver tumors have been evaluated: cryosurgical ablation (cryosurgery); radiofrequency ablation; laser ablation; transhepatic arterial embolization, chemoembolization, or radioembolization with yttrium-90 microspheres; microwave coagulation; and percutaneous ethanol injection. Cryosurgical ablation occurs in tissue that has been frozen by at least 3 mechanisms: (1) formation of ice crystals within cells, thereby disrupting membranes and interrupting cellular metabolism among other processes; (2) coagulation of blood, thereby interrupting blood flow to the tissue, in tum causing ischemia and apoptosis; and (3) induction of apoptosis.

Recent studies, including a small randomized controlled trial and case series, have reported on experience with cryosurgical and other ablative methods used in combination with subtotal resection and/or procedures such as transarterial chemoembolization.1,2

Procedure-Related Complications

Cryosurgery is not a benign procedure. Treatment-related deaths occur in approximately 2% of study populations and are most often caused by cryoshock, liver failure, hemorrhage,
pneumonia/sepsis, and acute myocardial infarction. Clinically significant nonfatal complication rates in the reviewed studies ranged from 0% to 83% and were generally due to the same causes as treatment-related deaths. The likelihood of complications arising from cryosurgery might be predicted, in part, by the extent of the procedure, but much of the treatment-related morbidity and mortality reflect the generally poor health status of patients with advanced hepatic disease.

**Literature Review**

This review was informed by a TEC Assessment (2000) that found insufficient data to permit conclusions on the effect of cryosurgery on health outcomes of patients with unresectable hepatocellular carcinoma (HCC), cholangiocarcinoma, or liver metastases.

Evidence reviews assess the clinical evidence to determine whether the use of technology improves the net health outcome. Broadly defined, health outcomes are the length of life, quality of life, and ability to function-including benefits and harms. Every clinical condition has specific outcomes that are important to patients and managing the course of that condition. Validated outcome measures are necessary to ascertain whether a condition improves or worsens, and whether the magnitude of that change is clinically significant. The net health outcome is a balance of benefits and harms.

To assess whether the evidence is sufficient to draw conclusions about the net health outcome of technology, two domains are examined: the relevance, and quality and credibility. To be relevant, studies must represent one or more intended clinical use of the technology in the intended population and compare an effective and appropriate alternative at a comparable intensity. For some conditions, the alternative will be supportive care or surveillance. The quality and credibility of the evidence depend on study design and conduct, minimizing bias and confounding that can generate incorrect findings. The randomized controlled trial (RCT) is preferred to assess efficacy; however, in some circumstances, nonrandomized studies may be adequate. RCTs are rarely large enough or long enough to capture less common adverse events and long-term effects. Other types of studies can be used for these purposes and to assess generalizability to broader clinical populations and settings of clinical practice.

**Hepatocellular Carcinoma**

**Clinical Context and Therapy Purpose**

The purpose of cryosurgical ablation (CSA) in patients who have unresectable primary HCC is to provide a treatment option that is an alternative to or an improvement on existing therapies.

The question addressed in this evidence review is: Does the use of CSA improve health outcomes for individuals with unresectable primary HCC?

The following PICO's were used to select literature to inform this review.

**Patients**

The relevant population of interest are individuals with unresectable primary HCC amenable to locoregional therapy.

**Interventions**

The therapy being considered is CSA.

**Comparators**

The following therapies are currently being used: radiofrequency ablation (RFA), microwave tumor ablation, and locoregional ablation other than RFA.
Outcomes
The general outcomes of interest are disease-free and overall survival (OS). Other outcomes include recurrence rates, symptom reductions, and treatment-related adverse events. Estimates for disease-related mortality can range from three to six months, and sometimes longer.

Randomized Controlled Trials
Wang et al (2015) reported on an RCT comparing cryoablation with RFA in 360 patients with HCC. One hundred eighty treatment-naive patients with Child-Pugh class A or B cirrhosis and one or two HCC lesions 4 cm or less and without metastasis were randomized to each treatment group. Of the 360 patients enrolled, 310 patients were ineligible for surgical resection due to significant portal hypertension. The median follow-up for the cryoablation group was 25 months (range, 8-64 months) and 25 months (range, 5-65 months) for the RFA group (p=0.767). At 1, 2, and 3 years, local tumor progression rates were 3%, 7%, and 7% for cryoablation and 9%, 11%, and 11% for RFA, respectively (p=0.043). OS rates at 1, 3, and 5 years for cryoablation were 97%, 67%, and 40% and 97%, 66%, and 38% for RFA, respectively (p=0.747). Tumor-free survival rates at 1, 3, and 5 years were 89%, 54%, and 35% in the cryoablation group and 84%, 50%, and 34% in the RFA group, respectively (p=0.628). Major complications were experienced in 7 (3.9%) patients following cryoablation and in 6 (3.3%) patients following RFA (p=0.776).

Overall, trial strengths included its randomized design, a well-characterized patient population with few dropouts, intention-to-treat analysis, and evaluation of clinical outcomes. However, there did not appear to be an accounting of the disposition of all patients approached for enrollment. Additionally, there was a suboptimal randomization scheme, lack of allocation concealment, and some evidence for noncomparability of groups at baseline. The lack of any local tumor progression after approximately 14 months (extrapolated from the graph) in either group seems unusual.

Nonrandomized Comparative Studies
Ei et al (2015) reported on outcomes for consecutive patients with primary HCC treated with cryotherapy (n=55) or RFA or microwave coagulation therapy (n=64) using prospectively collected data. The choice of locally ablative therapy was made by a multidisciplinary team based on the following criteria: cryoablation for tumors near major hepatic veins, hepatic hilum, secondary branches of the portal pedicles, or other organs; RFA or microwave coagulation therapy for tumors of 1 cm or less; and patient preference. Groups were similar at baseline, with the exception that patients treated with cryotherapy had a larger median tumor size (2.5 cm vs 1.9 cm, p<0.001). Rates of short-term complications did not differ significantly between groups. Over a median follow-up of 25 months, local recurrence-free survival was non significantly higher in the cryoablation group (80% vs 68%, p=0.20). In a multivariable model to predict local recurrence, receiving cryoablation was significantly associated with reduced risk of recurrence (adjusted hazard ratio, 0.3; 95% confidence interval, 0.1 to 0.9; p=0.02). For tumors greater than 2 cm in diameter, the 2-year local recurrence rate was lower for patients treated with cryoablation (21% vs 56%, p=0.006).

In a smaller, retrospective comparative study including 42 patients with HCC and cirrhosis, Dunne et al (2014) reported on short-term safety outcomes after cryoablation or RFA. Twenty-five patients underwent 33 cryoablation procedures, and 22 patients underwent 30 RFA procedures; 5 patients underwent both cryoablation and RFA procedures. No significant differences were observed in the overall complication rates, complication rates by severity, or specific complication types by cryoablation and RFA groups.

Noncomparative Studies
Noncomparative studies and systematic reviews of these studies have reported outcomes after the use of cryoablation for HCC. Although these studies may provide useful information about complications and longer-term recurrences after cryoablation, they do not provide evidence of the comparative effectiveness of cryoablation.
In a Cochrane review, Awad et al (2009) evaluated cryotherapy for HCC, identifying 2 prospective cohort studies and 2 retrospective studies but no RCTs or quasi-RCTs. This review antedates Wang et al (2015). Only one study could be considered for the assessment of benefit. In that study, Adam et al (2002) stratified results by both the type of hepatic malignancy (primary or secondary) and the intervention group (percutaneous cryotherapy or percutaneous RFA). Sixty-four patients were treated based on the random availability of probes: 31 patients received cryotherapy and 33 received RFA. Of all patients treated, 26 (84%) of 31 who had cryotherapy and 24 (73%) of 33 who had RFA developed a local recurrence, all within 1 year. The distribution of primary cancers was not specified. Among the HCC patients, rates of initial tumor ablation were similar after cryosurgery (65%) or RFA (76%) but local recurrences were more frequent after cryosurgery (38%) than after RFA (17%). Survival at 1 year did not differ by ablative technique (cryosurgery, 66% vs RFA, 61%). The trial did not include controls managed with an established alternative. Cochrane reviewers concluded that there was no evidence to recommend or refute cryotherapy in the treatment of patients with HCC.

Since the 2009 Cochrane review, several studies have reported on series of patients with HCC treated using cryoablation. Yang et al (2012) reported on 300 patients treated between 2003 and 2006 with percutaneous argon-helium cryoablation for HCC. Complete tumor ablation occurred in 185 tumors in 135 patients with mean tumor diameter of 5.6 cm, while 223 tumors in 165 patients with a mean tumor diameter of 7.2 cm were incompletely ablated (p<0.001). Serious complications occurred in 19 (6.3%) patients, including liver hemorrhage in 5 patients, cryoshock syndrome in 6 patients, gastric bleeding in 4 patients, liver abscess in 1 patient, and intestinal fistula in 1 patient. Liver failure resulted in the death of two patients. Patients with incomplete ablation received additional treatment with transcatheter embolization or a multikinase inhibitor (sorafenib). During the median follow-up of 36.7 months (range, 6-63 months), the local tumor recurrence rate was 31%. Larger tumors and tumor location were significantly related to tumor recurrence (p=0.029 and 0.037, respectively). The OS rates were 80% at 1 year, 45% at 2 years, and 32% at 3 years.

Rong et al (2015) reported on longer-term outcomes (median, 30.9 months) after cryoablation in a series of 866 patients with HCC treated at a single-center in China. A total of 832 (96.1%) patients were considered to have a complete response after up to 3 cryoablation sessions. During follow-up, 502 (60.2%) patients with an initial complete response had a recurrence (n=99 [11.9%] local, n=396 [44.5%] distant intrahepatic, n=7 [0.85%] extrahepatic). Two hundred sixteen subjects died (mortality rate, 25.9%), corresponding to a 5-year OS rate of 59.5%.

In a study not included in the 2009 Cochrane review, Zhou et al (2009) categorized 124 patients with primary nonresectable HCC into the early, middle, and advanced stage groups using Barcelona Clinic Liver Cancer staging classification. After argon-helium cryoablation, the serum level of α-fetoprotein was reduced in 76 (82.6%), and 205 (92.3%) of 222 tumor lesions were diminished or unchanged. Median survival time was 31.35 months in the early-stage, 17.4 months in the middle-stage, and 6.8 months in the late-stage groups. As of April 2008, 14 patients had survived and 110 had died. To determine risk factors that predict metastasis and recurrence, Wang et al (2009) also studied a series of 156 patients with hepatitis B virus-related HCC and tumors smaller than 5 cm in diameter who underwent curative cryoablation. One-, two-, and three-year OS rates were 92%, 82%, and 64% respectively, and 1-, 2-, and 3-year recurrence-free survival rates were 72%, 56%, and 43% respectively. The multivariate analysis showed that Child-Pugh class and expression of vascular endothelial growth factor in HCC tissues could be used as independent prognostic factors for OS. The expression of vascular endothelial growth factor in HCC tissues and hepatitis B virus basal core promoter variants were independent prognostic factors for recurrence-free survival.

Section Summary: HCC
The available RCT comparing cryoablation with RFA demonstrated lower rates of local tumor progression with cryoablation but no differences in survival outcomes between groups. Although this trial provided suggestive evidence that cryoablation is comparable to RFA, trial limitations...
would suggest findings need to be replicated. Additional comparative evidence is needed to permit conclusions about the effectiveness of cryoablation compared with other locoregional therapies.

**Neuroendocrine Cancer Liver Metastases**

Neuroendocrine tumors are relatively slow-growing malignancies (mean survival time, 5-10 years) that commonly metastasize to the liver. As with other cancers, the most successful treatment of hepatic metastasis is resection with tumor-free margins, but treatment benefits for a slow-growing tumor must be weighed against the morbidity and mortality of major surgery. The intent of cryosurgery in these cases is to minimize or eliminate symptoms caused by liver metastases while avoiding the complications of open surgery.

**Clinical Context and Therapy Purpose**

The purpose of CSA in patients who have unresectable liver metastases from neuroendocrine tumors is to provide a treatment option that is an alternative to or an improvement on existing therapies.

The question addressed in this evidence review is: Does the use of CSA improve health outcomes for individuals with unresectable liver metastases from neuroendocrine tumors?

The following PICOs were used to select literature to inform this review.

**Patients**

The relevant population of interest are individuals with unresectable liver metastases from neuroendocrine tumors amenable to locoregional therapy.

**Interventions**

The therapy being considered is CSA.

**Comparators**

The following therapies are currently being used: RFA, microwave tumor ablation, and locoregional ablation other than RFA.

**Outcomes**

The general outcomes of interest are disease-free and OS. Other outcomes include recurrence rates, symptom reductions, and treatment-related adverse events. Unlike other liver metastases, neuroendocrine tumors metastatic to the liver may cause systemic symptoms, including palpitations, flushing, and diarrhea, secondary to the release of neuropeptides. Given the nature of neuroendocrine tumors, treatment outcomes can be measured over a 5- to 10-year period.

**Systematic Reviews**

A Cochrane review by Gurusamy et al (2009) compared the benefits and harms of liver resection with those of other treatments in patients who had resectable liver metastases from gastro-entero-pancreatic neuroendocrine tumors. Trials comparing liver resection (alone or in combination with RFA or cryoablation) with other interventions (chemotherapy, hormonotherapy, or immunotherapy) and studies comparing liver resection with thermal ablation (RFA or cryoablation) were sought. Cochrane reviewers reported finding that none of the RCTs suitable for review nor any quasi-randomized, cohort, or case-control studies could inform meaningfully. No analysis was performed, and reviewers referred to only RFA in their discussion, noting that radiofrequency is not suitable for large tumors (i.e., >5-6 cm), and that neuroendocrine liver metastases are frequently larger than that. They concluded that randomized trials comparing surgical resection with RFA in selected patients would be appropriate.
Cohort Studies
Saxena et al (2012) retrospectively reviewed data on 40 patients treated with cryoablation and surgical resection for hepatic metastases from neuroendocrine cancer. The median period of follow-up was 61 months (range, 1-162 months). One death occurred within 30 days of treatment. No other complications were reported. Median survival was 95 months, and the rate of survival was 92%, 73%, 61%, and 40% at 1, 3, 5, and 10 years, respectively.

Chung et al (2001) reported on outcomes of cryosurgery for hepatic metastases from neuroendocrine cancer. This study used cytoreduction (resection, cryosurgery, RFA, or a combination of the three) and adjuvant therapy (octreotide, chemotherapy, radiotherapy, interferon-α) in 31 patients with neuroendocrine metastases to the liver and "progressive symptoms refractory to conventional therapy." Following treatment, symptoms were eliminated in 87% of patients; median symptom-free interval was 60 months with octreotide and 16 months with alternaties. Because outcomes were not reported separately for different cytoreductive techniques, it was not possible to compare the benefits of cryosurgery with those of other cytoreductive approaches or octreotide alone.

Section Summary: Neuroendocrine Cancer Liver Metastases
The available evidence for unresectable liver metastases from neuroendocrine tumors amenable to locoregional therapy is very limited. Current evidence does not permit conclusions on whether this technology affects health outcomes.

Liver Metastases From Colorectal Cancer
Although multiple tumor types metastasize to the liver, CRC is particularly likely to metastasize to the liver and has been the focus of the bulk of the literature on cryoablation for non-neuroendocrine tumor liver metastases.

Clinical Context and Therapy Purpose
The purpose of CSA in patients who have unresectable liver metastases from CRC is to provide a treatment option that is an alternative to or an improvement on existing therapies.

The question addressed in this evidence review is: Does the use of CSA improve health outcomes for individuals with unresectable liver metastases from CRC?

The following PICOs were used to select literature to inform this review.

Patients
The relevant population of interest are individuals with unresectable liver metastases from CRC amenable to locoregional therapy.

Interventions
The therapy being considered is CSA.

Comparators
The following therapies are currently being used: RFA, microwave tumor ablation, and locoregional ablation other than RFA.

Outcomes
The general outcomes of interest are disease-free and OS. Other outcomes include recurrence rates, symptom reductions, and treatment-related adverse events. Estimates for disease-related mortality can range up to two years, with subsets of populations surviving five to ten years.

Systematic Reviews
A Cochrane review by Al-Asfoor et al (2008) compared outcomes of resection of CRC liver metastases with no intervention or other treatment modalities, including RFA and cryosurgery. Only RCTs reporting on patients who had curative surgery for adenocarcinoma of the colon or...
rectum, who had been diagnosed with liver metastases, and who were eligible for liver resection were considered. Only 1 randomized trial by Korpan (1997) was identified, a trial from the Ukraine that compared surgical resection with cryosurgery in 123 subjects, 82 of whom had liver metastases from primary CRCs and the remainder who had metastases from other primary tumors. Survival outcomes were not provided by the type of cryogenic procedure or primary tumor site. Cochrane reviewers concluded that local ablative therapies were probably useful but that the therapy would need further evaluation in an RCT. A Cochrane review by Bale et al (2013) examined cryoablation for liver metastases from various sites, primarily colorectal. Only the Korpan (1997) RCT, included in the 2008 Cochrane review, met inclusion criteria. The Korpan (1997) trial was considered to have a high-risk of bias, and reviewers found the available evidence was insufficient to determine whether there were any benefits with cryoablation over conventional surgery or no intervention.

A Cochrane review by Gurusamy et al (2010) compared liver resection (alone or in combination with RFA or cryoablation) with nonsurgical treatments (neoadjuvant chemotherapy, chemotherapy, or RFA) in patients with colorectal liver metastases and hepatic node involvement. No RCTs, quasi-randomized trials, or cohort studies were identified to address this clinical scenario.

Pathak et al (2011) reported on a systematic review of ablative therapies for CRC liver metastases. They selected 26 nonrandomized studies on cryoablation. Reviewers reported local recurrence rates in the studies ranging from 12% to 39%. Survival rates ranged from 46% to 92% at 1 year, 8% to 60% at 3 years, and 0% to 44% at 5 years. Mean survival rates at 1, 3, and 5 years were 84%, 37%, and 17%, respectively. Major complications ranged from 7% to 66%. Cryoshock was indicated to be of major concern.

**Case Series**

A few studies have compared cryotherapy with other treatments for liver metastases. Ruers et al (2007) reported on a consecutive series of 201 CRC patients, without the extrahepatic disease, treated between 1995 and 2004 and who underwent laparotomy for surgical treatment of liver metastases. These patients were prospectively followed for survival and quality of life. During laparotomy, three groups were identified: patients in whom radical resection of metastases proved feasible, patients in whom resection was not feasible and received local ablative therapy (with or without resection), and patients in whom resection or local ablation was not feasible for technical reasons and who received systemic chemotherapy. The study reported that patients in the chemotherapy and local ablation groups were comparable for all prognostic variables tested. For the local ablation group, OS rates at 2 and 5 years were 56% and 27%, respectively (median, 31 months; n=45); for the chemotherapy group, 51% and 15%, respectively (median, 26 months; n=39; p=0.252). After resection, these rates were 83% and 51%, respectively (median, 61 months; n=117; p<0.001). Median disease-free survival (DFS) after local ablation was nine months. The authors concluded that although OS of local ablation vs chemotherapy was not statistically significant, median DFS of nine months suggested a beneficial effect of local tumor ablation. However, given the heterogeneity of the groups in this study, it is very difficult to compare outcomes among groups. Additionally, this study used both cryotherapy and RFA for local ablation, and results were reported for the combined group further limiting interpretation of specific results in cryoablation.

Niu et al (2007) analyzed data collected prospectively for 415 patients who underwent hepatic resection for metastatic CRC with or without cryoablation from 1990 to 2006. A decision about resectability was determined at the time of surgery. Patients who had resections and cryoablation were more likely to have bilobar disease (85% vs 27%, respectively) and to have 6 or more lesions (35% vs 3%, respectively). Additionally, 73% of this combined treatment group received hepatic arterial chemotherapy compared with 32% in the resection-only group. Median follow-up was 25 months (range, 1-124 months). The 30-day perioperative mortality rate was 3.1%. For the resection group, the median survival was 34 months, with 1-, 3-, and 5-year survival values rates of 88%, 47%, and 32%, respectively. The median survival for the resection plus
cryotherapy group was 29 months, with 1-, 3-, and 5-year survival rates of 84%, 43%, and 24%, respectively (p=0.206). The overall recurrence rate was 66% for resection only but 78% for resection plus cryotherapy. Five factors were independently associated with improved survival: the absence of extrahepatic disease at diagnosis, well- or moderately differentiated CRC, lesion size of 4 cm or less, a postoperative carcinoembryonic antigen of 5 ng/mL or less, and absence of liver recurrence. While the recurrence rates between groups did not differ, it is unclear how representative the patients who had resection plus cryotherapy were of the total sample of 415 patients. The comparability of the two groups is uncertain, especially given the differential use of hepatic arterial chemotherapy. In this study, a direct comparison was not made with chemotherapy. Finally, the 16-year duration of the study raises concerns about intercurrent changes that could have had affected the results.

In a relatively small study, Joosten et al (2005) reported on 58 patients with unresectable colorectal liver metastases where CSA or RFA was performed on patients ineligible for resection.25 Median follow-up was 26 and 25 months for CSA and RFA, respectively. One- and 2-year survival rates were 76% and 61% for CSA and 93% and 75% for RFA, respectively. In a lesion-based analysis, the local recurrence rate was 9% after CSA and 6% after RFA. Complication rates were 30% and 11% after CSA and RFA, respectively (p=0.052). While the small size of this study makes drawing conclusions difficult, results raise questions about the relative efficacy of both techniques.

A number of series have reported on outcomes for cryoablation for liver metastases from CRC. Summarized here are some of the larger and more recent series. Ng et al (2012) conducted a retrospective review of 293 patients treated between 1990 and 2009 for colorectal liver metastases with cryoablation with or without surgical resection.26 Perioperative death occurred in ten (3%) patients and included liver abscess sepsis in four patients, cardiac events unrelated to treatment in three patients, and one case each of dilated cardiomyopathy, cerebrovascular event, and multiorgan failure. Median follow-up was 28 months (range, 0.1-220 months). OS rates were 87%, 41.8%, 24.2%, and 13.3% at 1, 3, 5, and 10 years, respectively.

Seifert et al (2005) reported on a series of patients with colorectal liver metastases treated from 1996 to 2002.27 In this series, 168 patients underwent resection, and 55 had CSA (in 25 of these patients, it was combined with resection). Twenty-nine percent (16/55) of the ablation group had prior liver resection compared with only 5% in the resection group. Twenty percent of both groups had the extrahepatic disease at the time of surgery. With a median follow-up of 23 months, median and 5-year survival rates following resection and cryotherapy were comparable, with 29 months and 29 months and 23% and 26%, respectively. However, the median DFS times and 5-year DFS rates following resection were superior at 10 months and 19%, respectively, for resection compared with 6 months and 12%, respectively, for cryotherapy. Overall recurrence was 61% in the resection group and 76% in the cryotherapy group and liver recurrence was 45% and 71%, respectively. Study limitations included the small sample size, limited follow-up, and noncomparability of the groups.

Komprat et al (2007) reported on thermo ablation combined with resection in the treatment of hepatic metastasis from CRC.28 In this series, from 1998 to 2003, 665 patients with colorectal metastases underwent hepatic resection. Of these, 39 (5.9%) had additional intraoperative thermo ablative procedures (19 RFA, 20 CSA ). The overall morbidity rate was 41% (16/39). No RFA-related complications occurred; however, three patients developed an abscess at cryoablation sites. The median DFS was 12.3 months (range, 8.4-16.2 months). The local in situ recurrence rate according to the number of ablated tumors was 14% for RFA and 12% for CSA . Tumor size correlated directly with recurrence (p=0.02) in RFA-treated lesions.

Xu et al (2008) reported on a series of 326 patients with unresectable hepatic colorectal metastases treated with 526 percutaneous cryosurgery procedures.29 At 3 months post-treatment, carcinoembryonic antigen levels decreased to the normal range in 197 (77.5%) of patients who had elevated markers before cryosurgery. Among 280 patients who had
computed tomography follow-up, cryo-treated lesions showed complete response in 41 (14.6%) patients, partial response in 115 (41.1%), stable disease in 68 (24.3%), and disease progression in 56 (20%). During a median follow-up of 32 months (range, 7-61 months), the recurrence rate was 47.2%. The recurrence rate at the cryo-treated site was 6.4% for all cases.

During a median follow-up of 36 months, the median survival of all patients was 29 months (range, 3-62 months). OS rates were 78%, 62%, 41%, 34%, and 23% at 1, 2, 3, 4, and 5 years, respectively, after treatment. For patients with tumor sizes smaller than 3 cm, tumors in the right lobe of the liver, carcinoembryonic antigen levels less than 100 ng/dL, and post-cryosurgery transcatheter arterial chemoembolization had higher survival rates.

Section Summary: Liver Metastases From CRC
The available RCT comparing surgical resection with cryoablation was judged to be at high-risk of bias. Some nonrandomized comparative studies have reported improved survival outcomes for patients managed with cryotherapy compared with those managed with resection alone; however, these studies were subject to bias in the selection of patients for treatments. Additional controlled studies are needed to permit conclusions on the effectiveness of cryoablation compared with other locoregional therapies.

Summary of Evidence
For individuals who have unresectable primary HCC amenable to locoregional therapy who receive CSA, the evidence includes an RCT, several nonrandomized comparative studies, and multiple noncomparative studies. The relevant outcomes are OS, disease-specific survival, and treatment-related mortality and morbidity. The available RCT comparing cryoablation with RFA demonstrated lower rates of local tumor progression with cryoablation but no differences in survival outcomes between groups. Although this trial provided suggestive evidence that cryoablation is comparable with RFA, trial limitations would suggest findings need to be replicated. Additional comparative evidence is needed to permit conclusions about the effectiveness of cryoablation compared with other locoregional therapies. The evidence is insufficient to determine the effects of the technology on health outcomes.

For individuals who have unresectable liver metastases from neuroendocrine tumors amenable to locoregional therapy who receive CSA, the evidence includes a Cochrane review and case series. The relevant outcomes are OS, disease-specific survival, symptoms, and treatment-related mortality and morbidity. The available evidence base is very limited. The evidence is insufficient to determine the effects of the technology on health outcomes.

For individuals who have unresectable liver metastases from CRC amenable to locoregional therapy who have CSA, the evidence includes an RCT, several nonrandomized comparative and noncomparative studies, and systematic reviews of these studies. The relevant outcomes are OS, disease-specific survival, and treatment-related mortality and morbidity. The available RCT comparing surgical resection with cryoablation was judged at high-risk of bias. Some nonrandomized comparative studies have reported improved survival outcomes for patients managed with cryotherapy compared with those managed with resection alone; however, these studies were subject to bias in the selection of patients for treatments. Additional controlled studies are needed to permit conclusions about the effectiveness of cryoablation compared with other locoregional therapies. The evidence is insufficient to determine the effects of the technology on health outcomes.

Supplemental Information
Clinical Input From Physician Specialty Societies and Academic Medical Centers
While the various physician specialty societies and academic medical centers may collaborate with and make recommendations during this process, through the provision of appropriate reviewers, input received does not represent an endorsement or position statement by the physician specialty societies or academic medical centers, unless otherwise noted.
In response to requests from Blue Cross Blue Shield Association, input was received from 2 physician specialty societies and 3 academic medical centers in 2008. All reviewers supported the use of cryoablation for liver tumors and, in general, cited the studies reviewed in the Rationale section. Some reviewers considered cryoablation as one of several ablative techniques that could be used in these patients.

**Practice Guidelines and Position Statements**

The National Comprehensive Cancer Network (NCCN) indicates that ablative techniques may be used in the treatment of certain hepatic tumors. The NCCN guidelines on hepatobiliary cancer (v.2.2018) include cryoablation in a list of ablative techniques, along with radiofrequency ablation (RFA), percutaneous alcohol ablation, and microwave ablation; however, the literature cited in the guidelines reports on only RFA and ethanol ablation.30 For hepatocellular carcinoma, the NCCN makes the following category 2A recommendation: "All patients with HCC [hepatocellular carcinoma] should be evaluated for potential curative therapies (resection, transplantation, and for small lesions, ablative strategies). Locoregional therapy should be considered in patients who are not candidates for surgical curative treatments, or as a part of a strategy to bridge patients for other curative therapies.

Ablation (radiofrequency, cryoablation, percutaneous alcohol injection, microwave):

- All tumors should be amenable to ablation such that the tumor and, in the case of thermal ablation, a margin of normal tissue is treated. A margin is not expected following percutaneous ethanol injection.
- Tumors should be in a location accessible for percutaneous/laparoscopic/open approaches for ablation.
- Caution should be exercised when ablat ing lesions near major vessels, major bile ducts, diaphragm, and other intra-abdominal organs.
- Ablation alone may be curative in treating tumors ≤3 cm. In well-selected patients with small properly located tumors, ablation should be considered as definitive treatment in the context of a multidisciplinary review. Lesions 3 to 5 cm may be treated to prolong survival using arterially directed therapies, or with combination of an arterially directed therapy and ablation as long as tumor location is accessible for ablation.
- Unresectable/inoperable lesions >5 cm should be considered for treatment using arterially directed or systemic therapy.
- Sorafenib should not be used as adjuvant therapy post-ablation."

For intrahepatic cholangiocarcinoma (isolated intrahepatic mass), the guidelines recommend locoregional therapy using arterially directed therapies or external-beam radiotherapy (category 2B recommendations).

The NCCN guidelines on neuroendocrine and adrenal tumors (v.2.2018) address the use of hepatic-directed therapies for patients with unresectable hepatic-predominant progressive metastatic neuroendocrine.31 These guidelines support consideration of ablative therapies such as RFA or cryoablation if near-complete tumor burden can be achieved (category 2B recommendation).

The NCCN guidelines on the treatment of colon cancer with liver metastases (v.2.2018) consider patients with liver oligometastases as candidates for tumor ablation therapy. Ablative techniques include RFA, microwave ablation, cryoablation, percutaneous ethanol injection, and electro-coagulation. Use of surgery, ablation, or the combination "with the goal of less-than-complete resection/ablation of all known sites of disease, is not recommended" (category 2A recommendations).32

**U.S. Preventive Services Task Force Recommendations**

Not applicable.
Medicare National Coverage
There is no national coverage determination. In the absence of a national coverage determination, coverage decisions are left to the discretion of local Medicare carriers.

Ongoing and Unpublished Clinical Trials
A search of ClinicalTrials.gov in May 2018 did not identify any ongoing or unpublished trials that would likely influence this review.

**Coding**

This Policy relates only to the services or supplies described herein. Benefits may vary according to product design; therefore, contract language should be reviewed before applying the terms of the Policy. Inclusion or exclusion of codes does not constitute or imply member coverage or provider reimbursement.

**IE**

The following services may be considered investigational.

**Definitions of Decision Determinations**

**Medically Necessary:** Services that are Medically Necessary include only those which have been established as safe and effective, are furnished under generally accepted professional standards to treat illness, injury or medical condition, and which, as determined by Blue Shield, are: (a) consistent with Blue Shield medical policy; (b) consistent with the symptoms or diagnosis; (c) not furnished primarily for the convenience of the patient, the attending Physician or other provider; (d) furnished at the most appropriate level which can be provided safely and effectively to the patient; and (e) not more costly than an alternative service or sequence of services at least as likely to produce equivalent therapeutic or diagnostic results as to the diagnosis or treatment of the Member’s illness, injury, or disease.

**Investigational/Experimental:** A treatment, procedure, or drug is investigational when it has not been recognized as safe and effective for use in treating the particular condition in accordance with generally accepted professional medical standards. This includes services where approval by the federal or state governmental is required prior to use, but has not yet been granted.
**Split Evaluation:** Blue Shield of California/Blue Shield of California Life & Health Insurance Company (Blue Shield) policy review can result in a split evaluation, where a treatment, procedure, or drug will be considered to be investigational for certain indications or conditions, but will be deemed safe and effective for other indications or conditions, and therefore potentially medically necessary in those instances.

**Prior Authorization Requirements (as applicable to your plan)**

Within five days before the actual date of service, the provider must confirm with Blue Shield that the member's health plan coverage is still in effect. Blue Shield reserves the right to revoke an authorization prior to services being rendered based on cancellation of the member's eligibility. Final determination of benefits will be made after review of the claim for limitations or exclusions.

Questions regarding the applicability of this policy should be directed to the Prior Authorization Department at (800) 541-6652, or the Transplant Case Management Department at (800) 637-2066 ext. 3507708 or visit the provider portal at www.blueshieldca.com/provider.

Disclaimer: This medical policy is a guide in evaluating the medical necessity of a particular service or treatment. Blue Shield of California may consider published peer-reviewed scientific literature, national guidelines, and local standards of practice in developing its medical policy. Federal and state law, as well as contract language, including definitions and specific contract provisions/exclusions, take precedence over medical policy and must be considered first in determining covered services. Member contracts may differ in their benefits. Blue Shield reserves the right to review and update policies as appropriate.
