Policy Statement

Magnetic Resonance Imaging (MRI) for Screening Uses
MRI of the breast may be considered medically necessary for breast cancer screening of a patient with any of the following conditions:

I.  Lobular carcinoma in situ
II.  A known BRCA1 or BRCA2 variant
III.  High risk of BRCA1 or BRCA2 variant due to a known presence of the variant in relatives
IV.  Documentation of any of the following:
   A.  Gene variant associated with high risk, e.g., TP53 (Li-Fraumeni syndrome), PTEN (Cowden syndrome, Bannayan-Riley-Ruvalcaba syndrome), CDH1, and STK11, ATM, CHEK2, and PALB2
   B.  A first-degree relative with a gene variant associated with high risk, e.g., TP53 (Li-Fraumeni syndrome), PTEN (Cowden syndrome, Bannayan-Riley-Ruvalcaba syndrome), CDH1, and STK11, ATM, CHEK2, and PALB2
V.  High risk (lifetime risk about greater than or equal to 20% or 5-year risk of greater than or equal to 3%) of developing breast cancer as identified by models that are largely defined by family history
VI.  Received radiotherapy to the chest between 10 and 30 years of age

MRI for Detection Uses
MRI of the breast for detection may be considered medically necessary for any of the following:

I.  Suspected occult breast primary tumor in patient with axillary nodal adenocarcinoma (i.e., negative mammography and physical exam)
II.  A new diagnosis of breast cancer to evaluate the contralateral breast with both of the following:
   A.  Clinical exam is normal
   B.  Mammographic findings are normal

MRI for Treatment-Related Uses
MRI of the breast for treatment-related issues may be considered medically necessary for any of the following:

I.  Preoperative tumor mapping of the involved (ipsilateral) breast to evaluate the presence of multicentric disease in patient with clinically localized breast cancer who are candidates for breast conservation therapy
II.  Presurgical planning in patient with locally advanced breast cancer (before and after completion of neoadjuvant chemotherapy) to permit tumor localization and characterization
III.  To determine the presence of pectoralis major muscle/chest wall invasion in patient with posteriorly located tumors
IV.  To evaluate a documented abnormality of the breast before obtaining an MRI-guided biopsy when there is documentation that other methods, such as palpation or ultrasound, are not able to localize the lesion for biopsy

MRI of the breast is considered investigational for any of the following indications:

I.  Routine screening for an average risk patient
II.  Screening for breast cancer when the sensitivity of mammography (i.e., mammography using low-dose x-rays for imaging) is limited (i.e., dense breasts, breast implants, scaring after breast cancer treatment)
III. The test is to diagnose low-suspicion findings on conventional testing that are not indicated for immediate biopsy and referral for short-interval follow-up

IV. The test is to diagnose a suspicious breast lesion in order to avoid biopsy

V. Determining the level of response during neoadjuvant chemotherapy in patients with locally advanced breast cancer

VI. Evaluating for residual tumor in patients with positive margins after initial lumpectomy or breast conservation surgery

**Policy Guidelines**

**National Comprehensive Cancer Network (NCCN)**

**High-Risk Considerations**
There is no standardized method for determining a woman's risk of breast cancer that incorporates all possible risk factors. Clinical practice guidelines offer guidance on factors known to individually indicate a high risk of breast cancer (see the Supplemental Information section).

A number of factors may increase the risk of breast cancer but do not by themselves indicate high risk. It is possible that combinations of factors may be indicative of high risk, but it is not possible to quantitate estimates of risk. As a result, it may be necessary to individualize the estimate of risk, whereby one would need to take into account the numerous risk factors. A number of risk factors, not individually indicating high risk, are included in the National Cancer Institute Breast Cancer Risk Assessment Tool (also called the Gail model). Risk factors in the model can be accessed online (https://bcrisktool.cancer.gov/).

**General**
A first-degree relative is defined as the parents, brothers, sisters, or children of an individual.

**Considerations for Performing Magnetic Resonance Imaging**
Breast magnetic resonance imaging (MRI) exams should be performed and interpreted by an expert breast imaging team working with the multidisciplinary oncology treatment team.

Breast MRI exams require a dedicated breast coil and the use of contrast agents by radiologists familiar with the optimal timing sequences and other technical aspects of image interpretation. The breast MRI center also should have the ability to perform MRI-guided biopsy and/or wire localization of findings detected by MRI. Since these are standard, documentation is not needed for approval (unless something unusual is noted that is of concern). CPT codes 77048 (unilateral) or 77049 (bilateral) would be used for cancer detection.

**Considerations for Preoperative MRI**
Preoperative MRI in patients with localized disease results in higher rates of mastectomy and lower rates of breast-conserving therapy. There is uncertainty from the available evidence on whether outcomes are improved by changing to a more extensive operation. If biopsies are performed on all MRI-identified lesions, and if shared patient decision making is used for altering the surgical approach, then the probability of improved outcomes is increased.

Consideration of BRCA1 and BRCA2 gene mutation testing should be given for women who have a family history suspected of having the BRCA1 or BRCA2 mutation, which has not been identified. (For further reference see Blue Shield of California Medical Policy: Genetic Testing for Hereditary Breast and/or Ovarian Cancer Syndrome [BRCA1 or BRCA2]).

**Risk Assessment Tools**
A number of risk assessment tools based mainly on family history can assist practitioners in estimating breast cancer risk and include the Claus (1), modified Gail (2), Tyrer-Cuzick (3), and...
BRCAPRO (4) models. The National Cancer Institute (NCI) Breast Cancer Risk Assessment Tool\textsuperscript{74} is available at https://bcrisktool.cancer.gov/

**Note:** The tool should not be used to calculate breast cancer risk for women who have already had a diagnosis of breast cancer, lobular carcinoma in situ (LCIS), or ductal carcinoma in situ (DCIS).

**The Breast Imaging Reporting and Data System (BI-RADS) Classification**

The Breast Imaging Reporting and Data System (BI-RADS) provides a standardized classification system for mammograms\textsuperscript{75}:

<table>
<thead>
<tr>
<th>BI-RADS Category</th>
<th>Assessment</th>
<th>Clinical Management Recommendation(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>Incomplete</td>
<td>Additional imaging evaluation needed before final assessment</td>
</tr>
<tr>
<td>1</td>
<td>Negative</td>
<td>No lesion found (routine follow-up)</td>
</tr>
<tr>
<td>2</td>
<td>Benign finding</td>
<td>No malignant features; e.g. cyst (routine follow-up for age, clinical management)</td>
</tr>
<tr>
<td>3</td>
<td>Probably benign finding</td>
<td>Malignancy is highly unlikely, e.g. fibroadenoma (initial short interval follow-up)</td>

**Coding**

The following CPT codes describing magnetic resonance imaging of the breast replaced codes 77058 and 77059:

- **77046:** Magnetic resonance imaging, breast, without contrast material; unilateral
- **77047:** Magnetic resonance imaging, breast, without contrast material; bilateral
- **77048:** Magnetic resonance imaging, breast, without and with contrast material(s), including computer-aided detection (CAD real-time lesion detection, characterization and pharmacokinetic analysis), when performed; unilateral
- **77049:** Magnetic resonance imaging, breast, without and with contrast material(s), including computer-aided detection (CAD real-time lesion detection, characterization and pharmacokinetic analysis), when performed; bilateral

**Description**

Magnetic resonance imaging (MRI) of the breast is performed using scanners and intravenous imaging contrast agents in combination with specialized breast coils. This evidence review only addresses the use of breast MRI for clinical indications related to the detection or diagnosis of breast cancer.

**Related Policies**

- Magnetic Resonance Imaging to Monitor the Integrity of Silicone Gel-Filled Breast Implants

**Benefit Application**

Benefit determinations should be based in all cases on the applicable contract language. To the extent there are any conflicts between these guidelines and the contract language, the contract language will control. Please refer to the member's contract benefits in effect at the time of service to determine coverage or non-coverage of these services as it applies to an individual member.
Some state or federal mandates (e.g., Federal Employee Program [FEP]) prohibits plans from denying Food and Drug Administration (FDA)-approved technologies as investigational. In these instances, plans may have to consider the coverage eligibility of FDA-approved technologies on the basis of medical necessity alone.

### Regulatory Status

MRI of the breast can be performed using commercially available magnetic resonance scanners and intravenous magnetic resonance contrast agents. Specialized breast coils such as the Access Breast Coil 4/SMS (Confirma) and magnetic resonance-compatible equipment for performing biopsy have been developed and cleared for marketing by the U.S. Food and Drug Administration (FDA) through the 510(k) process. The FDA determined that these devices are substantially equivalent to predicate devices for use “in conjunction with a magnetic resonance imager (MRI) to produce diagnostic and interventional images of the breast, chest wall and axillary tissues that can be interpreted by a trained physician.”

### Rationale

#### Background

**Magnetic Resonance Imaging**

MRI of the breast can be used to screen, detect, and/or diagnosis of breast cancer. MRI can be used as a replacement for mammography screening, or as an additional imaging test alone, or in combination with other imaging modalities. Each potential use is described below.

#### Literature Review

Evidence reviews assess whether a medical test is clinically useful. A useful test provides information to make a clinical management decision that improves the net health outcome. That is, the balance of benefits and harms is better when the test is used to manage the condition than when another test or no test is used to manage the condition.

The first step in assessing a medical test is to formulate the clinical context and purpose of the test. The test must be technically reliable, clinically valid, and clinically useful for that purpose. Evidence reviews assess the evidence on whether a test is clinically valid and clinically useful. Technical reliability is outside the scope of these reviews, and credible information on technical reliability is available from other sources.

#### Screening Uses

**Screening Individuals at High-Risk of Breast Cancer**

**Clinical Context and Test Purpose**

Screening uses include screening for breast cancer in patients who are at high genetic risk for breast cancer. Magnetic resonance imaging (MRI) of the breast has been investigated as a screening tool in specific higher-risk subgroups of patients. First, it has been studied in patients considered to be at high genetic risk of breast cancer, such as women with known BRCA1 or BRCA2 genetic variants or with a family history consistent with a hereditary pattern of breast cancer. Screening for breast cancer often begins at an earlier age in these patients, and mammography is considered less sensitive in younger patients due to the prevalence of dense breast tissue.

The questions addressed in this portion of the evidence review:

- Does the use of MRI as an adjunct to screening for breast cancer improve the net health outcome of patients at high-risk of breast cancer compared with standard mammographic techniques?
- Is this degree of increased accuracy likely to improve net health outcomes via earlier diagnosis and treatment?
The following PICO was used to select literature to inform this review.

**Patients**  
The population of interest is patients at high-risk of developing breast cancer.

**Interventions**  
The intervention of interest is MRI as an adjunct to screening with mammography. Breast MRI is administered in an outpatient imaging facility or hospital setting.

**Comparators**  
The following test is currently being used to make decisions about managing breast cancer: mammography alone. Mammography is administered in an outpatient imaging setting.

**Outcomes**  
The outcomes of interest for diagnostic accuracy include test accuracy and test validity (i.e., sensitivity, specificity). Primary outcomes of interest for clinical utility are overall mortality and breast cancer-specific mortality. Another outcome of interest for clinical utility is resource utilization (e.g., need for additional testing or procedures).

MRI is performed as an adjunct to routine screening; timing can be guided by national guidelines on breast cancer screening (see Supplemental Information section).

**Study Selection Criteria**  
This evidence review focuses on systematic reviews. For the evaluation of the clinical validity of MRI as an adjunct to screening with mammography, we sought systematic reviews that focused on studies meeting the following eligibility criteria:

- Reported on the accuracy of the marketed version of the technology (including any algorithms used to calculate scores)
- Included a suitable reference standard (describe the reference standard)
- Patient/sample clinical characteristics were described
- Patient/sample selection criteria were described.

**Technically Reliable**  
Assessment of technical reliability focuses on specific tests and operators and requires a review of unpublished and often proprietary information. Review of specific tests, operators, and unpublished data are outside the scope of this evidence review and alternative sources exist. This evidence review focuses on the clinical validity and clinical utility.

**Clinically Valid**  
A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

**Systematic Reviews**  
The original evidence review was informed by a Blue Cross Blue Shield Association Technology Evaluation Center (TEC) Assessment (2003). This Assessment concluded that for high-risk women, the evidence appeared to show equivalent or better performance for MRI in terms of sensitivity in detecting breast cancer compared with mammography.

Three systematic reviews identified have included women at high-risk of developing breast cancer. Warner et al (2008) review included 11 studies published through 2008. Two reviews by Phi et al (2015, 2017) reported 2 individual patient data meta-analyses from the same 6 studies published between 2010 and 2013. Phi et al (2015) included the women with BRCA1 or BRCA2 variants and Phi et al (2017) included the women with a strong family history of breast cancer without a known variant. Characteristics of the systematic reviews are shown in Table 1.

MRI: magnetic resonance imaging.

Results of the systematic reviews are shown in Table 2. The reviews concluded that screening breast MRI is more sensitive but less specific than mammography for the detection of invasive cancers in high-risk women. The sensitivity of combined MRI and mammography was approximately 93% or higher in the reviews while the sensitivity of mammography alone was between approximately 40% and 55%. The Warner et al (2008) review did not present a risk of bias or quality assessment of included studies. Phi et al (2015) assessed quality using the QUADAS-2 tool. All included studies were considered good quality.

CI: confidence interval; MRI: magnetic resonance imaging; PE: pooled estimate.

Clinically Useful

A test is clinically useful if the use of the results informs management decisions that improve the net health outcome of care. The net health outcome can be improved if patients receive correct therapy, or more effective therapy, or avoid unnecessary therapy, or avoid unnecessary testing. The clinical usefulness of MRI as an adjunct to mammography for screening individuals at high risk of breast cancer is supported by an indirect chain of evidence. The clinical validity of MRI for screening in high-risk women has been demonstrated in good quality studies. MRI is more sensitive but less specific than mammography for detecting invasive cancers in high-risk women and the sensitivity of combined MRI and mammography is approximately 93% or higher. Given the high likelihood of malignancy among women at high-risk for breast cancer, the benefits of detecting cancer earlier with adjunctive MRI outweigh the disadvantages of incurring more unnecessary workups and biopsies due to false-positive results.

Section Summary: Screening Individuals at High-Risk of Breast Cancer

MRI is more sensitive than mammography in detecting malignancy during screening. Because of the high likelihood of malignancy among women at high-risk for breast cancer, the benefits of
detecting cancer earlier with adjunctive MRI outweigh the disadvantages of incurring more unnecessary workups and biopsies due to false-positive results.

**Screening Individuals at Average-Risk of Breast Cancer**

**Clinical Context and Test Purpose**

The questions addressed in this portion of the evidence review:

- Does the use of MRI as an adjunct to screening for breast cancer improve the net health outcome of patients who are asymptomatic with average-risk of developing breast cancer?
- Is this degree of increased accuracy likely to improve net health outcomes via the earlier diagnosis, and treatment?

The following PICO was used to select literature to inform this review.

**Patients**

The relevant population of interest is patients at average-risk of developing breast cancer.

**Interventions**

The intervention of interest is MRI as an adjunct to screening with mammography. Breast MRI is administered in an outpatient imaging facility or hospital setting.

**Comparators**

The following test is currently being used to make decisions about managing breast cancer: mammography alone. Mammography is administered in an outpatient imaging facility.

**Outcomes**

The outcomes of interest for diagnostic accuracy include test accuracy and test validity (i.e., sensitivity, specificity). Primary outcomes of interest for clinical utility are overall mortality and breast cancer-specific mortality. Another outcome of interest for clinical utility is resource utilization (e.g., need for additional testing or procedures).

MRI is performed as an adjunct to routine screening; timing can be guided by national guidelines on breast cancer screening (see Supplemental Information section).

**Study Selection Criteria**

The principles followed to select methodologically credible studies for this section are outlined in the first indication above.

**Technically Reliable**

This evidence review focuses only on the clinical validity and clinical utility for reasons explained in the first indication above.

**Clinically Valid**

A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

**Systematic Reviews**

In a systematic review of literature conducted by Nelson et al (2016) for the U.S. Preventive Services Task Force breast cancer screening recommendation update, no RCTs or nonrandomized observational studies identified evaluated adjunctive MRI for screening average-risk women for breast cancer. Because the prevalence of breast cancer is extremely low in average-risk young women, screening with a test such as MRI that has lower specificity would result in a lower positive predictive value (PPV) and many more false-positive results. Compared with mammography, there would be greater numbers of workups and biopsies with increased anxiety and morbidity with adjunctive MRI screening applied to young, average-risk women.
Health Quality Ontario (2016) published a systematic review of MRI as an adjunct to mammography for women, not at high-risk of breast cancer. Reviewers searched for studies evaluating screening breast MRI as an adjunct to mammography compared with mammography alone. Studies needed to use pathology results as a reference standard for positive tests and clinical follow-up as a reference standard for negative tests. In addition, studies needed to report one or more outcomes of interest, which included effectiveness outcomes (e.g., mortality, health-related quality of life, screening-related harms) and diagnostic outcomes (e.g., sensitivity, specificity), and biopsy and recall rates. Reviewers did not find any studies that met eligibility criteria. They concluded that there was a lack of evidence to inform the questions of the diagnostic accuracy of MRI plus mammography vs MRI alone and the impact of adjunct screening MRI on health outcomes in patients at less than high-risk of breast cancer.

**Section Summary: Screening of Individuals at Average-Risk of Breast Cancer**
The US Preventative Services Task Force systematic review and guideline concluded that because the prevalence of breast cancer is low in average risk young women, screening with MRI, which has lower specificity would result in a lower PPV and many more false positive results. A systematic review by Health Quality Ontario concluded that there was lack of evidence on the impact of MRI on health outcomes of individuals at less than high risk of breast cancer.

**Screening When Breast Characteristics Limit the Sensitivity of Mammography**

**Clinical Context and Test Purpose**
Screening MRI has been suggested for patients who may or may not be at increased risk but who have breast tissue characteristics that limit the sensitivity of mammographic screening (these characteristics are dense breast tissue, breast implants, or scarring after breast-conserving therapy [BCT]). BCT consists of breast-conserving surgery (BCS) followed by radiotherapy. The questions addressed in this portion of the evidence review:

- Does the use of MRI as an adjunct to screening for breast cancer improve the net health outcome of patients who are asymptomatic with breast characteristics that limit the sensitivity of mammography?
- Is this degree of increased accuracy likely to improve net health outcomes via the earlier diagnosis, and treatment?

The following PICO was used to select literature to inform this review.

**Patients**
The population of interest are patients with breast characteristics that limit the sensitivity of mammography. For example, individuals who have dense breasts or prior BCT.

**Interventions**
The intervention of interest is MRI as an adjunct to screening with mammography. Breast MRI is administered in an outpatient imaging facility or hospital setting.

**Comparators**
The following test is currently being used to make decisions about managing breast cancer: mammography alone. Mammography is administered in an outpatient imaging facility.

**Outcomes**
The outcomes of interest for diagnostic accuracy include test accuracy and test validity (i.e., sensitivity, specificity). Primary outcomes of interest for clinical utility are overall mortality and breast cancer-specific mortality. Another outcome of interest for clinical utility is resource utilization (e.g., need for additional testing or procedures).

MRI is performed as an adjunct to routine screening; timing can be guided by national guidelines on breast cancer screening (see the Supplemental Information section).
Study Selection Criteria
The principles followed to select methodologically credible studies for this section are outlined in the first indication above.

Technically Reliable
This evidence review focuses only on the clinical validity and clinical utility for reasons explained in the first indication above.

Clinically Valid
A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

Systematic Reviews
Evidence for individuals with a limited sensitivity of mammography was informed by a TEC Assessment (2004). & No systematic reviews were identified.

Randomized Controlled and Single Arm Studies: Dense Breasts
One RCT and a prospective observational study were identified that evaluated the use of supplemental MRI in patients who received screening mammography and/or ultrasound. Characteristics of the studies are shown in Table 3.

</table>
Results of the clinical validity studies are shown in Table 4. Bakker et al (2019) conducted a multicenter RCT (DENSE) with 40,373 women with extremely dense breast tissue and normal mammography results who were assigned to an optional supplemental MRI or mammography-only screening.9 There were 8061 patients invited to undergo MRI (MRI-invitation group); however, 4783 patients participated in supplemental MRI screening and 3278 chose not to participate. There were 32,312 patients who only received mammography (mammography-only group). The interval cancer rate was 2.5 per 1000 screenings in the MRI-invitation group compared to 5.0 per 1000 screenings in the mammography-only group (rate difference, 2.5; 95% confidence interval [CI], 1.0 to 3.7; p<0.001). Of note, among the 20 interval cancers diagnosed in the MRI-invitation group, 16 were diagnosed in patients who did not accept the supplemental MRI invitation (4.9 per 1000 screenings), while 4 were diagnosed in patients who underwent MRI screening (0.8 per 1000 screenings). In the 2012 ACRIN (American College of Radiology Imaging Network) 6666 trial, mammography alone was compared with mammography plus ultrasound in women 25 years or older with at least heterogeneous dense breast tissue and at least 1 other breast cancer risk factor.10 Half (54%) of women had a personal history of breast cancer. In an MRI subanalysis, women who completed 3 rounds of screening and did not have contraindications or renal impairment were asked to undergo contrast-enhanced MRI within 8 weeks of the last screening mammography. Six hundred twenty-seven women consented and were eligible for this subanalysis, and 612 (98%) completed the needed tests; 16 cancers were detected in these women. Sensitivity increased from 44% (95% CI, 20% to 70%) for mammography plus ultrasound to 100% (95% CI, 79% to 100% p =0.004) when MRI was added. Specificity declined from 84% (95% CI, 81% to 87%) for mammography plus ultrasound to 65% (95% CI, 61% to 69% p<0.001) for all 3 tests. Over the 3 year study period, another 9 cancers were identified between screening tests, and 2 additional cancers were identified off-study.

Observational Studies: Following Breast-Conserving Therapy

Two prospective studies have reported on the performance of surveillance breast MRI following BCT. Study characteristics are shown in Table 7. Both studies were performed in Korea and it is unclear whether the populations overlapped.

Table 7. Characteristics of Clinical Validity Studies Assessing Surveillance Breast MRI After BCT

|----------------|-------------------------------------------------|------------------|------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------|-----------------------|-----------------------------------|
| Kim et al (2017)\[^{12}\] | Women in Korea undergoing surveillance breast MRI following BCT from 2014 to 2016 | Prospective observational | - Pathology for positive results  
- Cancer not confirmed at 1-y surveillance imaging for negative results | Assessed as BI-RADS category 4 or 5 by 1 radiologist with 10+ y of experience in breast MRI | MRI within 4 wk of screening mammography and breast US | No (readers knew results of prior imaging studies) | Funded by Bayer Korea |
| Cho et al (2017)\[^{11}\] | Women aged ≤50 y in Korea undergoing surveillance breast MRI following BCT from 2010 to 2016 | Prospective observational | - Pathology for positive results  
- Cancer not confirmed at 1-y surveillance imaging for negative results | Assessed as BI-RADS category 3+ by 1 radiologist with 5+y of experience in breast MRI | MRI within 2 mo of screening mammography and breast US | Yes | Funded by Bayer Korea  
Overlap with Kim (2017) unclear |

BCT: breast-conserving therapy; BI-RADS: Breast Imaging Reporting and Data System; MRI: magnetic resonance imaging; US: ultrasound.

Results of the clinical validity studies for surveillance of breast MRI following BCT are shown in Table 8. The sensitivity of MRI was higher than mammography and ultrasound with overlapping CIs in both studies. Specificity of MRI was lower than mammography and ultrasound. The combination of mammography and MRI was 100% sensitive and 87% specific. The review by Cho et al (2017) reported that the recall rate was significantly higher for mammography plus MRI (13.8%; 95% CI, 12.0% to 15.5%) compared with mammography (4.4%; 95% CI, 3.3% to 5.5%), as was the biopsy rate (2.7% [95% CI, 2.0% to 3.4%] vs 0.5 [95% CI, 0.2% to 0.8%]). The yield per 1000 examinations was 8.2 (95% CI, 4.3 to 12.2) for mammography plus MRI vs 4.4 (95% CI, 1.5 to 7.2) for mammography.\[^{11}\]

Section Summary: Screening When Breast Characteristics Limit the Sensitivity of Mammography

The RCT from the Netherlands (Bakker 2019) found that among women with dense breasts, the use of MRI increased the cancer detection rate and decreased the interval cancer rate compared to mammography. However, the false positive rate was 79.8 per 1000 screenings. The trial is continuing in order to assess the effects over time of adjunctive screening with MRI. The prospective cohort trial by the American College of Radiology Imaging Network (ACRIN 6666; Berg 2012) found that the addition of MRI resulted in high cancer detection, but with increased false positive findings. The evidence is insufficient to show that the use of adjunctive MRI to screen average risk individuals who have dense breasts improves the net health outcome.

Two studies assessed the addition of MRI to mammography for surveillance of women who had been treated for cancer with BCT. The sensitivity of adjunct MRI was greater than mammography alone, but with overlapping confidence intervals. The companion study of women under 50 years showed higher cancer detection rates with adjunct MRI but lower specificity than mammography alone; the authors suggested that adjunctive mammography improves detection of early stage but biologically aggressive cancer in the population of younger women. However, to the extent that younger women may constitute a higher risk population, the delineation of MRI for screening high risk individuals is addressed in high risk screening section of this policy. The evidence is insufficient to demonstrate that adjunctive MRI for screening improves the net health outcome when breast characteristics limit the sensitivity of mammography.

Detection Uses
Detecting Suspected Occult Breast Primary Tumor With Axillary Nodal Adenocarcinoma With a Negative Mammography and Physical Exam

Clinical Context and Test Purpose
Breast MRI has been advocated to help detect suspected occult primary breast cancer in patients with adenocarcinoma in the axillary lymph nodes after mammography and physical exam have failed to reveal a breast tumor. Localization of a primary breast tumor might permit BCT instead of presumptive mastectomy.

The questions addressed in this portion of the evidence review:
- Does the use of MRI as an adjunct to detect breast cancer eligible for BCT improve the net health outcome compared to standard techniques in individuals with suspected occult breast primary tumor with axillary nodal adenocarcinoma and negative mammography?
- Is this degree of increased accuracy likely to improve net health outcomes via the earlier diagnosis, better patient management decisions, and more appropriate treatment?

The following PICO was used to select literature to inform this review.

Patients
The population of interest is individuals with suspected occult breast primary tumor with axillary nodal adenocarcinoma and negative mammography.

Interventions
The intervention of interest is MRI examination as an adjunct to detect breast cancer eligible for BCT. Breast MRI is administered in an outpatient imaging facility or hospital setting.
Comparators
The comparator of interest is a preemptive mastectomy, which is performed in a hospital setting.

Outcomes
The outcomes of interest for diagnostic accuracy include test accuracy and test validity (i.e., sensitivity, specificity). Primary outcomes of interest for clinical utility are the avoidance of invasive procedures (e.g., biopsy, mastectomy), the ability to detect cancer that would require additional or earlier treatment, and overall mortality and breast cancer-specific mortality rates.

MRI is performed after a positive breast cancer screening or diagnostic examination.

Study Selection Criteria
For the evaluation of the clinical validity of MRI as an adjunct to detect breast cancer eligible for BCT, studies that met the following eligibility criteria were considered:
• Reported on the accuracy of the marketed version of the technology (including any algorithms used to calculate scores)
• Included a suitable reference standard
• Patient/sample clinical characteristics were described
• Patient/sample selection criteria were described.

Technically Reliable
This evidence review focuses only on the clinical validity and clinical utility for reasons explained in the first indication above.

Clinically Valid
A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

De Besser et al (2010) evaluated 8 retrospective studies in a systematic review of studies on the use of MRI in patients (N = 220 patients) with mammographically occult breast cancer and an axillary metastasis. In 7 studies, a potential primary lesion was detected in a mean of 72% of cases (range, 36% to 86%). Pooling individual patient data yielded a sensitivity of 90% (range, 85% to 100%) in detecting an actual malignant tumor. Specificity, however, was 31% (range, 22% to 50%).

Clinically Useful
A test is clinically useful if the use of the results informs management decisions that improve the net health outcome of care. The net health outcome can be improved if patients receive correct therapy, or more effective therapy, or avoid unnecessary therapy, or avoid unnecessary testing.

Direct Evidence
Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. Because these are intervention studies, the preferred evidence would be from RCTs.

Evidence on detection of suspected occult breast cancer is based on a TEC Assessment (2004) and a subsequent meta-analysis. The Assessment concluded that, in this small subgroup of patients, adjunctive use of breast MRI allowed a substantial portion of patients (25% to 61%) to avoid the morbidity of mastectomy; risk of the unnecessary biopsy was estimated to be 8%.

Section Summary: Detecting Suspected Occult Breast Primary Tumor With Axillary Nodal Adenocarcinoma With a Negative Mammography and Physical Exam
The use of MRI to guide BCS rather than presumptive mastectomy appears to offer the substantial benefit of breast conservation for those patients in whom MRI detects the primary tumor.
Detecting Contralateral Breast Cancer After Established Breast Cancer

Clinical Context and Test Purpose
Patients with a diagnosed breast cancer are at higher risk for a synchronous or subsequent breast cancer in the contralateral breast, and breast MRI has been suggested as a more sensitive screening test compared to mammography.

The questions addressed in this portion of the evidence review:

• Does the use of MRI as an adjunct to detect breast cancer in the contralateral breast improve the net health outcome compared to standard techniques in individuals with suspected occult breast primary tumor with axillary nodal adenocarcinoma and negative mammography?
• Is this degree of increased accuracy likely to improve net health outcomes via the earlier diagnosis, better patient management decisions, and more appropriate treatment?

The following PICO was used to select literature to inform this review.

Patients
The population of interest is individuals with breast cancer.

Interventions
The intervention of interest is MRI examination as an adjunct to detect breast cancer in the contralateral breast. Breast MRI is administered in an outpatient imaging facility or hospital setting.

Comparators
The comparator of interest is mammography and clinical assessment alone, which are administered in an imaging facility or in a clinical setting.

Outcomes
The outcomes of interest for diagnostic accuracy include test accuracy and test validity (i.e., sensitivity, specificity). Primary outcomes of interest for clinical utility are the avoidance of invasive procedures (e.g., biopsy, mastectomy), the ability to detect cancer that would require additional or earlier treatment, and overall mortality and breast cancer-specific mortality rates.

MRI is performed after a positive breast cancer screening or diagnostic examination.

Study Selection Criteria
For the evaluation of the clinical validity of MRI examination as an adjunct to detect breast cancer in the contralateral breast, studies that met the following eligibility criteria were considered:

• Reported on the accuracy of the marketed version of the technology (including any algorithms used to calculate scores)
• Included a suitable reference standard (describe the reference standard)
• Patient/sample clinical characteristics were described
• Patient/sample selection criteria were described

Technically Reliable
This evidence review focuses only on the clinical validity and clinical utility for reasons explained in the first indication above.

Clinically Valid
A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

Single Arm Studies
Lehman et al (2007) reported on the results of the ACRIN-A6667 trial. They found that 30 (3%) of 969 women with a recent diagnosis of unilateral breast cancer had contralateral cancer at the time of initial diagnosis using MRI. Contralateral lesions were not detected by mammography or
physical exam. Eighteen (60%) of the 30 cancers were invasive and 12 (40%) were ductal carcinoma in situ (DCIS). In this study, 121 (12.5%) patients had biopsies, with a positive biopsy rate of 24.8%. With 1-year follow-up, the sensitivity of MRI was 91% and specificity was 88%. Results of this trial in a diverse group of patients were similar to the findings of others.

Liberman et al (2003) reported on 212 women who had negative mammograms of the asymptomatic contralateral breast and found 12 cancers (prevalence, 5%) on MRI, including 6 DCIS and 6 infiltrating carcinomas. However, the PPV of these findings was only 20%, with a specificity of 76%. Lehman et al (2005) found 4 contralateral cancers in 103 patients; in this study, 10 biopsies were done.

**Clinically Useful**
A test is clinically useful if the use of the results informs management decisions that improve the net health outcome of care. The net health outcome can be improved if patients receive correct therapy, or more effective therapy, or avoid unnecessary therapy, or avoid unnecessary testing.

**Direct Evidence**
Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. Because these are intervention studies, the preferred evidence would be from RCTs.

No RCTs assessing diagnostic breast MRI in individuals with suspected contralateral breast cancer after established breast cancer were identified.

**Chain of Evidence**
Indirect evidence on clinical utility rests on clinical validity. If the evidence is insufficient to demonstrate test performance, no inferences can be made about clinical utility.

A trial with nearly 1000 women found that MRI had high sensitivity and reasonably high specificity for identifying contralateral lesions not detected by mammography or physical examination. Although long-term outcomes of contralateral breast cancers are not fully known, important management changes will occur based on such findings, and these management changes should lead to improved outcomes.

**Section Summary: Detecting Contralateral Breast Cancer After Established Breast Cancer**
The available evidence suggests that adjunctive MRI can identify contralateral breast cancers in women with negative mammograms. A trial with nearly 1000 women found that MRI had high sensitivity and reasonably high specificity for identifying contralateral lesions not detected by mammography or physical examination. Although long-term outcomes of contralateral breast cancers are not fully known, important changes in management will occur as a result of the findings, and these management changes should lead to improved outcomes. That is, in addition to the presumed benefits of early detection, simultaneous treatment of synchronous cancers can occur rather than multiple treatments on separate occasions.

**Detecting Breast Cancer in the Case of Low-Suspicion Findings on Conventional Mammography**
Clinical Context and Test Purpose
Patients with abnormal findings on mammography are categorized according to the level of suspicion of the findings. Patients with low-suspicion findings are often recommended to undergo short-interval follow-up after 3 to 6 months (instead of immediate biopsy). This follow-up may continue for 2 years to demonstrate the stability of benign findings or to detect progression; progression would indicate the need for biopsy. MRI of the breast has been investigated as a more sensitive technique to further characterize low-suspicion breast lesions, so that patients with MRI-negative lesions may be reassured and avoid prolonged follow-up and those with MRI-positive lesions may be referred for early biopsy, possibly leading to earlier diagnosis and treatment. The question addressed in this portion of the evidence review: In patients with a diagnosis of low-suspicion findings on conventional testing not indicated for immediate biopsy, are net health...
outcomes improved by the use of MRI as an adjunct compared to standard care with short-interval mammographic follow-up to detect breast cancer?

The following PICO was used to select literature to inform this review.

**Patients**
The population of interest is individuals with low-suspicion findings on conventional mammography.

**Interventions**
The intervention of interest is MRI examination as an adjunct to standard care with short-interval mammographic follow-up. Breast MRI is administered in an outpatient imaging facility or hospital setting.

**Comparators**
The comparator of interest is standard care and short-interval mammographic follow-up, which is administered in an imaging facility or hospital setting.

**Outcomes**
The outcomes of interest for diagnostic accuracy include test accuracy and test validity (i.e., sensitivity, specificity). Primary outcomes of interest for clinical utility are the avoidance of invasive procedures (e.g., biopsy, mastectomy), the ability to detect cancer that would require additional or earlier treatment, and overall mortality and breast cancer-specific mortality rates.

MRI is performed after a positive breast cancer screening or diagnostic examination.

**Study Selection Criteria**
For the evaluation of the clinical validity of MRI examination as an adjunct to standard care with short-interval mammographic follow-up, studies that met the following eligibility criteria were considered:

- Reported on the accuracy of the marketed version of the technology (including any algorithms used to calculate scores)
- Included a suitable reference standard (describe the reference standard)
- Patient/sample clinical characteristics were described
- Patient/sample selection criteria were described.

**Technically Reliable**
This evidence review focuses only on the clinical validity and clinical utility for reasons explained in the first indication above.

**Clinically Valid**
A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

See the Clinically Useful section for discussion.

**Clinically Useful**
A test is clinically useful if the use of the results informs management decisions that improve the net health outcome of care. The net health outcome can be improved if patients receive correct therapy, or more effective therapy, or avoid unnecessary therapy, or avoid unnecessary testing.

**Direct Evidence**
Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. Because these are intervention studies, the preferred evidence would be from RCTs.
Evidence on low-suspicion findings is based on a TEC Assessment (2004). Available evidence has suggested that adjunctive MRI may be very sensitive and specific in patients with low-suspicion findings on conventional testing and may provide a useful method to select patients for biopsy or to avoid prolonged short-interval follow-up. However, none of the available studies used prospective methods appropriate to patient populations to directly compare the sensitivity and specificity of short-interval mammographic follow-up with MRI and to determine the effects of adjunctive MRI on cancer detection rate and biopsy rate.

**Chain of Evidence**

Indirect evidence on clinical utility rests on clinical validity. If the evidence is insufficient to demonstrate test performance, no inferences can be made about clinical utility.

Because the clinical validity of adjunctive MRI has not been establishing, a chain of evidence supporting the clinical utility of this modality cannot be constructed.

**Section Summary: Detecting Breast Cancer in the Case of Low-Suspicion Findings on Mammography**

A TEC Assessment found insufficient evidence on the use of MRI to diagnose low-suspicion findings on conventional testing that are not indicated for an immediate biopsy. Well-designed prospective confirmatory studies would be necessary to permit conclusions on the effect this adjunctive use of breast MRI on health outcomes.

**Detecting Breast Cancer by Further Characterizing Suspicious Breast Lesions**

**Clinical Context and Test Purpose**

Breast lesions detected by clinical exam or mammography that are considered suspicious are frequently referred for biopsy; however, only a minority of such biopsies reveal breast cancer due to the relatively low specificity of clinical and radiologic exams. Breast MRI has been investigated as a technique to further characterize suspicious breast lesions so that patients with benign lesions may be spared a biopsy procedure. One infrequent situation (niche use) in which MRI of the breast may be helpful and improve health outcomes is in the management of patients who have a suspicious lesion that can only be seen on one mammographic view (i.e., the lesion cannot be seen in other views or on an ultrasound). Patients who fall under this category have a lesion that is not palpable, and therefore, percutaneous biopsy localization cannot be performed. Instead, MRI would be used to localize the suspicious lesion and permit biopsy (this technique would presumably lead to earlier diagnosis of breast cancer as opposed to waiting until the lesion was visible on 2 mammographic views or on ultrasound). The previously described scenario is an infrequent occurrence, so the evidence base addressing this use is mainly anecdotal but the clinical rationale supporting this use is good.

The question addressed in this portion of the evidence review: Does MRI as an adjunct to further characterize breast lesions lead to better net health outcomes than biopsy based on mammography and clinical assessment?

The following PICO was used to select literature to inform this review.

**Patients**

The population of interest is individuals with suspicious breast lesions.

**Interventions**

The intervention of interest is MRI examination as an adjunct to mammography and clinical assessment. Breast MRI is administered in an outpatient imaging facility or hospital setting.

**Comparators**

The comparator of interest is biopsy based on mammography and clinical assessment, which is administered in an outpatient imaging facility, clinic, or hospital setting.
Outcomes
The outcomes of interest for diagnostic accuracy include test accuracy and test validity (i.e., sensitivity, specificity). Primary outcomes of interest for clinical utility are the avoidance of invasive procedures (e.g., biopsy, mastectomy), the ability to detect cancer that would require additional or earlier treatment, and overall mortality and breast cancer-specific mortality rates.

MRI is performed after a positive breast cancer screening or diagnostic examination.

Study Selection Criteria
For the evaluation of the clinical validity of MRI examination as an adjunct to mammography and clinical assessment, studies that met the following eligibility criteria were considered:
- Reported on the accuracy of the marketed version of the technology (including any algorithms used to calculate scores)
- Included a suitable reference standard (describe the reference standard)
- Patient/sample clinical characteristics were described
- Patient/sample selection criteria were described.

Technically Reliable
This evidence review focuses only on the clinical validity and clinical utility for reasons explained in the first indication above.

Clinically Valid
A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

Systematic Reviews
Evidence on further characterization of suspicious breast lesions was summarized in 3 TEC Assessments (2000, 2001, 2004). Studies addressed a group of patients who have breast lesions of sufficient suspicion to warrant a recommendation to undergo biopsy for diagnosis. Therefore, MRI results were assumed to have an impact on the decision of whether to undergo definitive biopsy, considered the criterion standard.

A systematic review published by Medeiros et al (2011) analyzed 69 studies including 9298 women. Pooled sensitivity was 90% (95% CI, 88% to 92%), and pooled specificity was 75% (95% CI, 70% to 79%). The pooled positive likelihood ratio of an abnormal MRI for malignancy was 3.6 (95% CI, 3.0 to 4.2) and the pooled negative likelihood ratio was 0.12 (95% CI, 0.09 to 0.15). For breast cancer or high-risk lesions vs benign lesions, the area under the curve for MRI was 0.91.

Single Arm Studies
Two single-institution, prospective cohort studies examined the diagnostic accuracy of breast MRI for lesions identified by mammography or ultrasound. Strobel et al (2015) in Germany included lesions characterized as BI-RADS category 4 by conventional workup in 340 women. Most women were postmenopausal (61%), had no previous breast biopsy (64%), or family history of breast cancer (62%), and underwent initial evaluation for routine screening (88%). Of 353 lesions, 135 (38%) were biopsied; lesions down-graded to BI-RADS categories 1, 2, or 3 on MRI were followed with imaging for 18 months, except for pure clustered microcalcifications (without accompanying mass), which were biopsied or followed with imaging for 24 months at patient discretion; none of the lesions monitored progressed during follow-up. The overall incidence of malignancy including DCIS was 20% (n=69). MRI down-graded 256 (28%) of 353 lesions, confirmed 37 (11%) lesions, and upgraded 50 (14%) lesions. The PPV of MRI was 73% compared with 19% for conventional imaging. The NPV of MRI was 99% (and could not be calculated for conventional imaging). For pure clustered microcalcifications, sensitivity was 89% (25/28 lesions) and the false-negative rate was 12% (3/28 lesions). False-positive MRI findings resulted in a biopsy for 5 (1.5%) of 340 women.
In a similar study, Li et al (2014) in China included 84 women with BI-RADS categories 3, 4, or 5 microcalcifications on mammography. Most patients were premenopausal (81%), had no family history of breast cancer (83%), and underwent initial evaluation for routine screening (56%). All lesions were biopsied surgically (n=91). The incidence of malignancy including DCIS was 46%. The PPV of MRI was 87% compared with 60% for mammography. The NPV of the MRI was 91%.

**Clinically Useful**
A test is clinically useful if the use of the results informs management decisions that improve the net health outcome of care. The net health outcome can be improved if patients receive correct therapy, or more effective therapy, or avoid unnecessary therapy, or avoid unnecessary testing.

**Direct Evidence**
Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. Because these are intervention studies, the preferred evidence would be from RCTs.

No RCTs assessing diagnostic breast MRI in individuals to further characterize suspicious breast lesions were identified.

**Chain of Evidence**
Indirect evidence on clinical utility rests on clinical validity. If the evidence is insufficient to demonstrate test performance, no inferences can be made about clinical utility.

Available evidence has not shown this use of breast MRI would improve health outcomes. Considering the relative ease of breast biopsy, the sensitivity of breast MRI would have to be virtually 100% to confidently avoid biopsy. Although MRI performs well, it is clear that the sensitivity is not 100%. False-negative results tend to occur, particularly in certain subcategories, such as DCIS, but invasive carcinomas may not be detected on MRI, also leading to false-negative results. The potential harm to health outcomes of failing to diagnose breast cancer or at least of delaying the diagnosis of breast cancer is of significant concern.

**Section Summary: Detecting Breast Cancer by Further Characterizing Suspicious Breast Lesions**
MRI for evaluation of suspicious breast lesions has relatively high sensitivity and a moderately high specificity. However, it has not yet been established whether the NPV is sufficient to preclude the need for biopsy. Although 2 more recent studies have reported NPVs greater than 90% in certain types of breast lesions, these studies were conducted in single, non-U.S. institutions that require replication in larger, multicenter trials. Therefore, the use of MRI to further characterize suspicious lesions is currently unlikely to alter clinical management. In addition, the fairly high rate of false-positives will lead to substantial numbers of unnecessary biopsies.

**Treatment-Related Uses**
Treatment-related uses addressed here are surgical planning, evaluating tumor response to neoadjuvant therapy, and evaluating residual tumor after BCT. Preoperative planning includes identification of multicentric disease in clinically localized breast cancer; surgical decisions after neoadjuvant chemotherapy; evaluation of suspected chest wall involvement, and localizing lesions prior to biopsy.

For each of these indications, study selection prioritized systematic reviews focusing on the relevant patient population and purpose. Systematic reviews were supplemented by studies of clinical validity. For the evaluation of clinical validity of MRI examination for the proposed purpose, studies that met the following eligibility criteria were considered:

- Reported on the accuracy of the marketed version of the technology (including any algorithms used to calculate scores)
- Included a suitable reference standard (describe the reference standard)
- Patient/sample clinical characteristics were described
- Patient/sample selection criteria were described.
In addition, we sought studies of clinical usefulness. These are studies that report the outcomes of using MRI for the proposed purpose, with preference for randomized controlled trials.

**Objective: Surgical Planning**

The question addressed in this portion of the evidence review is whether the use of MRI evaluation as an adjunct to guide treatment planning (e.g., surgical approach) for patients with known or suspected breast cancer improves the net health outcome compared with standard techniques. The sections on surgical planning address 4 specific indications: (1) identification of multicentric disease in clinically localized breast cancer; (2) surgical decisions after neoadjuvant chemotherapy; (3) evaluation of suspected chest wall involvement; and (4) localizing lesions prior to biopsy.

**Preoperative Mapping to Identify Multicentric Disease With Clinically Localized Breast Cancer**

**Clinical Context and Test Purpose**

Patients with clinically localized breast cancer are considered candidates for BCS followed by radiotherapy. However, mastectomy may be considered in patients with the multicentric disease (in a separate quadrant of the breast). MRI has been investigated as a technique to assess the extent of the tumor in the breast, specifically to detect the multicentric disease as an aid to surgical planning.

The question addressed in this evidence review: Does the use of MRI for preoperative mapping to identify multicentric disease improve net health outcomes?

The following PICO was used to select literature to inform this review.

**Patients**

The populations of interest is individuals with clinically localized breast cancer.

**Interventions**

The intervention of interest is MRI as an adjunct to standard evaluation methods. Breast MRI is administered in an outpatient imaging facility or hospital setting.

**Comparators**

The following tests and practices are currently being used to make decisions about managing breast cancer: standard workup without MRI. These comparators are administered in an imaging facility or in a clinical setting.

**Outcomes**

Relevant outcomes of interest for diagnostic accuracy include test accuracy and test validity (i.e., sensitivity, specificity). Primary outcomes of interest for clinical utility include avoidance of invasive procedures (e.g., biopsy, mastectomy), the ability to detect cancer requiring additional or earlier treatment, and overall mortality and breast cancer-specific mortality rates.

MRI is performed after identification of suspicious breast lesions, or before or after treatment for breast cancer.

**Systematic Reviews**

Evidence on preoperative mapping was based on a TEC Assessment (2004). The TEC Assessment concluded that ipsilateral MRI at the time of diagnosis did not meet TEC criteria because there was insufficient evidence to permit conclusions about the effect on health outcomes of adding MRI to the standard staging workup of early-stage invasive breast cancer. However, as noted in the Assessment, long-term recurrence rates after modified radical mastectomy compared with BCS plus whole-breast irradiation did differ, with lower long-term recurrence rates after mastectomy.
Subsequently, several meta-analyses have evaluated evidence on additional disease detected by MRI and changes in clinical management, most of which were by the same research group. The most recent and comprehensive meta-analysis was published by Houssami et al (2017). Studies included in the review were comparative (randomized or nonrandomized), evaluated preoperative MRI vs an alternative approach that did not include MRI, and reported quantitative data on surgical outcomes. The primary endpoint for the meta-analysis was whether patients underwent mastectomy as surgical treatment. Secondary endpoints were re-excision rates after BCS, positive margins after BCS, and receipt of contralateral prophylactic mastectomy. Nineteen studies met the inclusion criteria—3 RCTs and 16 nonrandomized comparative studies. For the primary study endpoint, a pooled analysis of 15 studies (n=85,975 patients) found significantly greater odds of receiving a mastectomy after preoperative MRI than after no MRI (odds ratio [OR], 1.39; 95% CI, 1.23 to 1.57; p<0.001). Findings were the same in analyses stratified by publication dates, suggesting that the higher mastectomy rates were not limited to older studies conducted when the MRI-guided biopsy was less common. In an analysis limited to patients with invasive lobular cancer, there was no significant difference in the odds of mastectomy (6 studies: pooled OR, 1.00; 95% CI, 0.75 to 1.33; p=0.988) or the odds of re-excision (5 studies: OR, = 0.65; 95% CI, 0.35 to 1.24; p=0.192).

Among the secondary outcomes, a pooled analysis of 3 studies found a significantly higher odds of contralateral prophylactic mastectomy after MRI (OR, =1.91; 95% CI, 1.25 to 2.91). There were no significant differences between groups on other secondary outcomes (i.e., re-excision rates, positive margins, reoperation rates).

One meta-analysis has addressed breast cancer recurrence rates. This meta-analysis, by Houssami et al (2014), analyzed individual patient data from 4 studies—1 RCT and 3 nonrandomized comparative studies (N=3180 patients). Most patients (62% to 93%) had localized, invasive disease and received BCT and systemic chemotherapy. After a median follow-up of 2.9 years (interquartile range [IQR], 1.6 to 4.5 years), there was no difference in estimated 8-year ipsilateral local (adjusted hazard ratio [HR], 0.88; 95% CI, 0.52 to 1.51; p=0.65) or distant (adjusted HR, 1.18; 95% CI, 0.76 to 2.27; p=0.48) recurrence-free survival overall or in patients who received BCT only.

**Randomized Controlled Trials**

A discussion of the 3 RCTs included in the Houssami et al (2017) meta-analysis (described above) is as follows.

Since the publication of the Houssami et al (2017) meta-analysis, Bruck et al (2018) reported on the results of an RCT to evaluate the diagnostic value of preoperative MRI in 100 patients with newly diagnosed unifocal stage I invasive ductal carcinoma. Patients were randomized in a 1:1 ratio to preoperative breast MR or surgery without MRI. Breast MRI detected an additional finding in 14 patients (28%) and MRI detected lesions in 7 (14%) of patients undergoing MRI were confirmed to be malignant. Seven (14%) patients underwent breast reoperation in the MRI group compared with 12 (24%) patients in the control group (p=0.20). Definitive mastectomy was performed in 6 (12%) patients in the MRI group compared with 2 (4%) in the control group (p=0.14).

The RCT by Gonzalez et al (2014) in Sweden assessed 440 women who underwent surgical treatment of invasive breast cancer with or without presurgical breast MRI. Breast MRI provided incremental information that altered treatment plan in 40 (18%) of 220 patients in the MRI group. Conversion from planned BCS to mastectomy occurred more often in the MRI group (20%) than in the control group (10%; p=0.024). However, more patients in the MRI group had planned BCS at baseline (70%) than in the control group (60%; p=0.036). The ipsilateral reoperation rate was 5% in the MRI group vs 15% in the control group (p<0.001). Reoperation rates among those initially planned for BCS were 5% and 22%, respectively (p<0.001).

A second RCT, the preoperative MRI and surgical management in patients with nonpalpable breast cancer trial, was reported by Peters et al (2011). It randomized 463 patients with suspicious, nonpalpable breast lesions identified by mammography or ultrasound to prebiopsy MRI.
or usual care. Of 207 evaluable patients in the MRI group, 11 additional suspicious lesions were identified on MRI and were occult on other imaging studies. All 11 additional lesions underwent biopsy, with 2 (18%) positive for malignancy. The incidence of mastectomy was similar between groups (32% vs 34%, p = 0.776), as was the incidence of BCS (68% vs 66%). The incidence of re-excisions due to positive tumor margins was significantly greater in the MRI group (34%) than in the control group (12%, p = 0.008).

A multicenter RCT from the U.K., Comparative effectiveness of MRI in breast cancer trial, reported by Turnbull et al (2010), examined the impact of presurgical MRI on the need for additional treatment within 6 months.31 This study was an open, parallel-group trial conducted at 45 centers in the U.K. and enrolled 1623 women with biopsy-proven breast cancer who were scheduled for wide local excision BCT. Of 816 patients in the MRI group, 58 (7%) underwent mastectomy as a result of MRI findings and/or patient choice, compared with 10 (1%) patients in the no-MRI group who underwent mastectomy by patient choice. There was no statistically significant reduction in reoperation rates in those who received MRI scans (19% in both groups; OR, 0.96; 95% CI, 0.75 to 1.24; p = 0.77). In the MRI group, 19 (2%) patients had a “pathologically avoidable” mastectomy, defined as a mastectomy based on MRI results showing more extensive disease but histopathology showing only localized disease. Twelve months after surgery, there was no statistically significant difference in the quality of life between groups.

Observational Studies
In addition to the RCTs, Onega et al (2018) reported on the association between preoperative MRI and all-cause mortality in 5 registries (N = 4454 patients) of the National Cancer Institute-sponsored Breast Cancer Surveillance Consortium.32 Data from the Breast Cancer Surveillance Consortium registries were linked to Medicare claims data or electronic health records; women ages 66 years and older with initial nonmetastatic breast cancer (stage I to III) diagnosed from 2005 to 2010 were included with follow-up continuing through 2014. Nine hundred seventeen (21%) women underwent preoperative MRI. The unadjusted 5-year cumulative probability of death was 0.12 for women with MRI and 0.17 for those without (HR, 0.67; 95% CI, 0.54 to 0.82). However, after adjustment for age, sociodemographic, and clinical factors, the association was attenuated (HR, 0.90; 95% CI, 0.72 to 1.12).

Fortune-Greeley et al (2014) retrospectively examined case records of 20,332 women with invasive breast cancer in the Surveillance Epidemiology and End Results-Medicare-linked dataset.33 Twelve percent of patients had a preoperative MRI. Among patients with invasive lobular carcinoma, but no other histologic types, preoperative breast MRI was associated with lower odds of reoperation after initial partial mastectomy (adjusted OR, 0.59; 95% CI, 0.40 to 0.86).

Section Summary: Preoperative Mapping to Identify Multicentric Disease With Clinically Localized Breast Cancer
Preoperative MRI as an adjunct to mammography and clinical assessment identifies additional foci of ipsilateral breast cancer and results in a higher rate of mastectomy. For example, a 2017 meta-analysis of 17 studies found significantly higher odds of receiving a mastectomy after preoperative MRI vs no MRI in women with breast cancer. Follow-up studies have reported mixed results, including no significant reduction in reoperations rates after MRI while other studies have reported lower odds of reoperation in patients with invasive lobular carcinoma. No significant differences in ipsilateral local or distant recurrence-free survival after MRI-guided treatment were found in meta-analyses. While there is limited evidence that use of MRI to identify multicentric disease improves recurrence free survival or reduces operations in the overall population, benefit might accrue to subpopulations, particularly high risk individuals.

Guiding Surgical Decisions After Neoadjuvant Chemotherapy
Clinical Context and Test Purpose
Patients with locally advanced breast cancer are usually offered neoadjuvant chemotherapy to reduce tumor size and permit BCT. Evaluation of tumor size and extent using conventional techniques (i.e., mammography, clinical examination, ultrasonography) is suboptimal, and breast
MRI has been proposed as a means to more accurately determine tumor size for surgical planning. MRI before chemotherapy is used to document tumor location so that the tumor can be optimally evaluated after chemotherapy, especially if the size and degree of contrast enhancement are greatly reduced. Tumors that respond to chemotherapy get smaller and may even disappear; however, the actual reduction in size is a delayed finding, and earlier changes in tumor vascularity have been observed in chemotherapy-responsive tumors. A decline in contrast enhancement on MRI has been noted in tumors relatively early in the course of chemotherapy. This MRI finding as an early predictor of tumor response has been explored as a means to optimize the choice of the chemotherapeutic agent (e.g., to alter chemotherapy regimen if the tumor appears unresponsive).

The question addressed in this evidence review: Does the use of MRI for guiding surgical decisions after neoadjuvant chemotherapy in patients with locally advanced breast cancer improve net health outcomes?

The following PICO was used to select literature to inform this review.

**Patients**
The population of interest is individuals with locally advanced breast cancer undergoing neoadjuvant chemotherapy.

**Interventions**
The intervention of interest is MRI to guide surgical decisions after neoadjuvant chemotherapy. Breast MRI is administered in an outpatient imaging facility or hospital setting.

**Comparators**
The following tests and practices are currently being used to make decisions about managing breast cancer: mammography and clinical assessment. These comparators are administered in an imaging facility or in an outpatient or a clinical setting.

**Outcomes**
Relevant outcomes of interest for diagnostic accuracy include test accuracy and test validity (i.e., sensitivity, specificity). Primary outcomes of interest for clinical utility include avoidance of invasive procedures (e.g., biopsy, mastectomy), the ability to detect cancer requiring additional or earlier treatment, and overall mortality and breast cancer-specific mortality rates.

MRI is performed after identification of suspicious breast lesions, or before or after treatment for breast cancer.

**Systematic Reviews**
Evidence on guiding surgical decisions is based on a TEC Assessment (2004), and more recent publications. Compared with conventional methods of evaluating tumor size and extent (i.e., mammography, clinical exam, ultrasound), MRI of the breast provides an estimation of tumor size and extent that is at least as good as or better than that based on alternatives. Drew et al (2001) found MRI to be 100% sensitive and specific for defining residual tumor after chemotherapy. Conversely, mammography achieved 90% sensitivity and 57% specificity (mammography results considered equivocal), and the clinical exam was only 50% sensitive and 86% specific. Similarly, Partridge et al (2002) reported on correlations of residual tumor size by histopathology of 0.89 with MRI and 0.60 with a clinical exam. MRI results were well-correlated with results of the histopathologic assessment (criterion standard) with correlation coefficients ranging from 0.72 to 0.98; however, MRI is not intended as a replacement for histopathologic assessment.

Several systematic reviews have been published since the 2004 TEC Assessment. Most recently, Marinovich et al (2015) published an individual patient data meta-analysis of agreement between MRI and pathologic tumor size and other evaluation methods after neoadjuvant chemotherapy. To be eligible for inclusion, studies had to evaluate at least 15 patients.
undergoing neoadjuvant chemotherapy who were evaluated with MRI and at least 1 other test (i.e., mammography, ultrasound, clinical examination) after surgery. Studies also had to report residual tumor size (i.e., longest diameter). Twenty-four studies met inclusion criteria, and individual patient data were available for 8 of these studies (N = 300 patients). The pooled mean difference (MD) in size estimates between MRI and pathology (8 studies, n = 243 patients) was 0.0 cm; 95% CI, -0.1 to 0.2 cm). In 4 studies comparing size estimates of mammography and pathology, the MD was 0.0 cm but the 95% CI was wider (-0.3 to 0.4 cm). In 5 studies (n = 123 patients) reporting on the MD between ultrasound and pathology, the pooled estimate was -0.3 cm (95% CI, -0.6 to 0.1 cm). The largest size variance was for studies (3 studies, n = 107 patients) comparing clinical examination with pathology (pooled MD = -0.8 cm; 95% CI, -1.5 to -0.1 cm).

Previously, Lobbes et al (2013) reported on a systematic review of 35 studies (N = 2359 patients) reporting on the ability of MRI to predict tumor size after neoadjuvant chemotherapy. Literature was searched to July 2012. Median correlation coefficient was 0.70 (range, 0.21 to 0.98). Variation in size between MRI and pathology ranged from -1.4 to +2.0 cm.

Section Summary: Guiding Surgical Decisions After Neoadjuvant Chemotherapy

Studies, including a 2015 meta-analysis, have found that MRI results are well-correlated with pathologic assessment for measuring residual tumor size after neoadjuvant chemotherapy and that MRI performed better than conventional methods. Using breast MRI instead of conventional methods to guide surgical decisions regarding BCT vs mastectomy after neoadjuvant chemotherapy would be at least as beneficial and might lead more frequently to appropriate surgical treatment.

Evaluating Suspected Chest Wall Involvement

Clinical Context and Test Purpose

Tumors located near the chest wall may invade the pectoralis major muscle or extend deeper into chest wall tissues. Typically, modified radical mastectomy removes only the fascia of the pectoralis muscle; however, tumor involvement of the muscle would also necessitate the removal of the muscle (or a portion of it). In smaller tumors, it is necessary to determine how closely the tumor abuts the pectoralis muscle and whether it invades the muscle to determine whether there is an adequate margin of normal breast tissue to permit BCT. Breast MRI has been suggested as a means of determining pectoralis muscle/chest wall involvement for surgical planning and to assist in the decision whether to use neoadjuvant chemotherapy.

The question addressed in this evidence review: Does the use of MRI to diagnose chest wall involvement of posteriorly located breast tumors improve net health outcomes?

The following PICO was used to select literature to inform this review.

Patients
The population of interest is individuals with posteriorly located breast tumors.

Interventions
The intervention of interest is MRI to diagnose chest wall involvement. Breast MRI is administered in an outpatient imaging facility or hospital setting.

Comparators
The following tests and practices are currently being used to make decisions about managing breast cancer: mammography. Mammography is administered in an outpatient imaging facility.

Outcomes
Relevant outcomes of interest for diagnostic accuracy include test accuracy and test validity (i.e., sensitivity, specificity). Primary outcomes of interest for clinical utility include avoidance of invasive procedures (e.g., biopsy, mastectomy), the ability to detect cancer requiring additional or earlier treatment, and overall mortality and breast cancer-specific mortality rates.
MRI is performed after identification of suspicious breast lesions, or before or after treatment for breast cancer.

**Observational Studies**
Morris et al (2000) prospectively studied 19 patients with posteriorly located breast tumors suspected to involve the pectoralis major muscle based on either mammography or clinical exam. Thirteen tumors were thought to be fixed to the chest wall on clinical exam, and 12 appeared to have pectoral muscle involvement on mammography. MRI results were compared with surgical and pathologic findings. The presence of abnormal enhancement within the pectoralis major muscle on MRI was 100% sensitive and 100% specific for identifying 5 tumors that actually involved the pectoralis major muscle.

Two other retrospective studies have reported on 4 cases in which MRI was able to determine the involvement of the chest wall with 100% accuracy.

**Section Summary: Evaluating Suspected Chest Wall Involvement**
Evidence on MRI for evaluating suspected chest wall involvement with posteriorly located tumors is based on prospective and retrospective observational studies. All studies found that MRI was able to detect chest wall involvement with 100% accuracy. Given the high level of diagnostic accuracy for MRI compared with criterion standard and conventional alternative techniques, the evidence is considered sufficient to conclude that breast MRI improves net health outcome.

**Evaluating and Localizing Lesions Prior to Biopsy**

**Clinical Context and Test Purpose**
The question addressed in this evidence review: Does the use of MRI to evaluate and localize breast lesions prior to biopsy improve net health outcomes?

The following PICOs were used to select literature to inform this review.

**Patients**
The populations of interest are individuals with a suspicious breast lesion recommended for biopsy but not localizable by mammography or ultrasonography.

**Interventions**
The intervention of interest is MRI to evaluate and localize breast lesion prior to biopsy. Breast MRI is administered in an outpatient imaging facility or hospital setting.

**Comparators**
The following tests and practices are currently being used to make decisions about managing breast cancer: waiting until lesion becomes palpable or visible on mammography or ultrasonography, which are administered in an outpatient imaging facility.

**Outcomes**
Relevant outcomes of interest for diagnostic accuracy include test accuracy and test validity (i.e., sensitivity, specificity). Primary outcomes of interest for clinical utility include avoidance of invasive procedures (e.g., biopsy, mastectomy), the ability to detect cancer requiring additional or earlier treatment, and overall mortality and breast cancer-specific mortality rates.

MRI is performed after identification of suspicious breast lesions recommended for biopsy.

**Observational Study**
Use of MRI to evaluate lesions prior to biopsy is infrequent. MRI is used in this situation to permit biopsy and breast cancer diagnosis sooner than waiting until the lesion is visible on 2 mammographic views or on ultrasound or becomes palpable. The evidence base addressing this use is mainly anecdotal.
De Lima Docema et al (2014) used contrast-enhanced MRI to locate occult tumors in 25 patients selected from a group who had undergone breast MRI for suspicious incidental MRI findings at a single-institution in Brazil. Sentinel lymph node mapping and tumor resection were done simultaneously. Malignant tumors were confirmed in 15 (60%) patients, including 4 patients with DCIS. Survival outcomes were not reported.

Section Summary: Evaluating and Localizing Lesions Prior to Biopsy
A small cohort study in Brazil identified malignant tumors in 60% of patients with MRI-detected occult lesions using contrast-enhanced MRI.

Evaluating Response to Neoadjuvant Chemotherapy With Locally Advanced Breast Cancer Clinical Context and Test Purpose
The question addressed in this evidence review: Does the use of MRI to evaluate response to chemotherapy for locally advanced breast cancer improve net health outcomes?

The following PICO was used to select literature to inform this review.

Patients
The population of interest is individuals with locally advanced breast cancer undergoing neoadjuvant chemotherapy.

Interventions
The intervention of interest is MRI to evaluate the response to chemotherapy. Breast MRI is administered in an outpatient imaging facility or hospital setting.

Comparators
The comparator of interest is clinical assessment alone.

Outcomes
Relevant outcomes of interest for diagnostic accuracy include test accuracy and test validity (i.e., sensitivity, specificity). Primary outcomes of interest for clinical utility include avoidance of invasive procedures (e.g., biopsy, mastectomy), the ability to detect cancer requiring additional or earlier treatment, and overall mortality and breast cancer-specific mortality rates.

MRI is performed after a period of undergoing adjuvant chemotherapy.

Systematic Reviews
The use of MRI to assess response to chemotherapy was addressed in a 2004 TEC Assessment and subsequent studies. Three systematic reviews of MRI to evaluate response to neoadjuvant chemotherapy have been published. Characteristics of the reviews are shown in Table 11 and described briefly in the following paragraphs. Li et al (2018) compared the performance of MRI with positron emission tomography (PET) plus computed tomography (CT).

Magnetic Resonance Imaging for Detection and Diagnosis of Breast Cancer

Study | Dates | Studies | Participants | N (Range) | Design | Reference Standard
--- | --- | --- | --- | --- | --- | ---
Lobbes et al (2013) | Up to 2012 | 8 | Newly diagnosed breast cancer for whom breast MRI was not performed at baseline or prior to surgery but after completion of NAC with at least 25 patients | 560 (31 to 195) | Observational (prospective, retrospective) | NR

CT: computed tomography; MRI: magnetic resonance imaging; NAC: neoadjuvant chemotherapy; NR: not reported; pCR: pathologic complete response; PET: positron emission tomography.

Results of the systematic reviews are shown in Table 12. Li et al (2018) reported on a systematic review comparing MRI with PET/CT to evaluate pathologic response to neoadjuvant chemotherapy and included studies in which patients underwent both PET/CT and MRI after preoperative neoadjuvant chemotherapy, postoperative pathologic complete response (pCR vs non-pCR) was used as the reference standard, and the study included at least 10 patients. Methodologic quality was assessed using QUADAS-2. Most domains were rated as low-risk of bias in all studies; however, only 2 studies enrolled consecutive or random samples and in only 3 studies were the reference standard results interpreted without knowledge of the results of the index tests. There was a high level of heterogeneity in the pooled estimate of both sensitivity (88% 95% CI, 78 to 94; $I^2=83\%$) and specificity (69% 95% CI, 51 to 83; $I^2=72\%$) for MRI.

Marinovich et al (2013) conducted a systematic review with meta-analysis. Forty-four studies (N =2949 patients) assessing the ability of MRI to discriminate residual breast tumor after neoadjuvant chemotherapy from pCR were identified. Studies were heterogeneous in MRI parameters used, thresholds for defining a response, and definitions of pathologic response. Median MRI sensitivity, defined as the proportion of patients with residual tumor correctly classified by MRI, and specificity, defined as the proportion of patients with pCR classified by MRI as the absence of residual tumor, was 0.92 (IQR, 0.85 to 0.97) and 0.60 (IQR, 0.39 to 0.96), respectively. Specificity increased when a relative threshold for defining negative MRI (i.e., contrast enhancement was less than or equal to normal breast tissue) was used rather than an absolute threshold (complete absence of MRI enhancement) with little decrement to sensitivity. The pooled area under the receiver operating characteristic curve was 0.88, and the diagnostic OR was 17.9 (95% CI, 11.5 to 28.0). (A diagnostic OR of 1 indicates no discriminatory ability; higher values indicate better test performance.) Accuracy decreased when residual DCIS was included in the definition of pCR. Statistical measures of between-study heterogeneity were not reported. A subset of studies compared MRI with other imaging modalities (mammography, ultrasound) and clinical exam; however, 95% CIs for pooled analyses were very large, rendering conclusions uncertain.

In the systematic review by Lobbes et al (2013), 8 studies reported on measures of diagnostic accuracy. Median sensitivity, defined as the proportion of patients with pCR correctly classified by MRI, was 42% (range, 25% to 92%). Median specificity, defined as the proportion of patients without pCR correctly classified by MRI, was 89% (range, 50% to 97%). Median (range) PPV and NPV were 64% (50% to 73%) and 87% (71% to 96%), respectively.

Trials
The ACRIN 6657/I-SPY trial (2012) enrolled 206 women aged 26 to 68 years with invasive breast cancer 3 cm or larger who were receiving anthracycline-based neoadjuvant chemotherapy, with or without a taxane. MRI was performed at 4 time points: before chemotherapy, after 1 cycle of chemotherapy, between the anthracycline-based regimen and the taxane, and after all chemotherapy but before surgery. Various MRI parameters were evaluated for their ability to predict the pathologic outcome. Results were reported as the difference in the predictive ability for residual cancer burden, a composite pathologic index, between MRI parameters and clinical size predictors at the same time points. MRI findings were a stronger predictor of pathologic outcomes than clinical assessment, with the largest difference being tumor volume after the first chemotherapy cycle and a difference in the area under the receiver operating characteristic curve of 0.09; the corresponding area under the receiver operating characteristic curve values after the third and fourth MRIs were 0.07 and 0.05. Similar findings were reported for predicting pCR.

Section Summary: Evaluating Response to Neoadjuvant Chemotherapy With Locally Advanced Breast Cancer
Studies, including systematic reviews, have not found sufficient evidence to determine whether breast MRI can reliably predict lack of response to neoadjuvant chemotherapy. There is a large amount of variability in reported performance characteristics of MRI in published studies, leaving uncertain the true accuracy of MRI for this purpose. Furthermore, evidence would need to show that any resulting change in patient management (e.g., discontinuation of chemotherapy or change to a different regimen) would improve outcomes.

Evaluating Residual Tumor After Lumpectomy or Breast Conservation Surgery
Clinical Context and Test Purpose
BCT includes complete removal of the primary tumor along with a rim of normal surrounding tissue. Pathologic assessment of surgical margins is performed on excisional specimens to determine whether the tumor extends to the margins of resection. Surgical specimens are oriented and marked to direct re-excision if margins are shown to contain tumor; however, when the tumor is not grossly visible, the extent of a residual tumor within the breast can only be determined through repeat excision and pathologic assessment. MRI has been proposed to evaluate the presence and extent of the residual tumor as a guide to re-excision when surgical margins are positive for tumor.

The question addressed in this evidence review: Does the use of MRI to evaluate residual tumor after lumpectomy or BCT improve net health outcomes?

The following PICO was used to select literature to inform this review.

Patients
The population of interest are individuals with positive surgical margins after lumpectomy or BCT.

Interventions
The intervention of interest is MRI to evaluate the residual tumor. Breast MRI is administered in an outpatient imaging facility or hospital setting.
Comparators
The comparator of interest is pathologic inspection, which is performed in a laboratory setting.

Outcomes
Relevant outcomes of interest for diagnostic accuracy include test accuracy and test validity (i.e., sensitivity, specificity). Primary outcomes of interest for clinical utility include avoidance of invasive procedures (e.g., biopsy, mastectomy), the ability to detect cancer requiring additional or earlier treatment, and overall mortality and breast cancer-specific mortality rates.

MRI is performed after lumpectomy or BCT.

Observational Studies
Evidence on evaluating residual tumor includes several observational studies, most of which are retrospective.46,47,49,50,51,52,53,54 Histopathologic examination on re-excision was used as the criterion standard. Three studies were conducted at the same institution and accrued patients during similar time periods, so overlap reporting may exist.47,49,50 Most of the studies were published before 2005 and are not discussed further. Characteristics of studies published since 2015 are shown in Table 13 and described briefly in the following paragraphs.51,52

| Krammer et al (2017)51 | Women with positive margins after initial surgery for breast cancer, from 2004 to 2013 | Retrospective | Histopathology | - Read independently by 2 radiologists
                                                      - Criteria for suspected residual disease: asymmetric thickening or nodular enhancement with irregular or speculated margins or extensive focal non-mass enhancement | NR | Radiologists had access to other imaging results, when available |

LCIS: lobular carcinoma in situ; MRI: magnetic resonance imaging; NR: not reported.

Results of the clinical validity studies published after 2015 are shown in Table 14. Lee et al (2018) reported on the results of a study comparing breast MRI with ultrasonography for detecting remnant lobular carcinoma in situ lesions after initial excision.52 Twenty-nine patients with lobular carcinoma in situ were enrolled between 2011 and 2015. Methods are poorly described. Residual lesions were identified by pathology in 12 (41%) cases. The sensitivity of ultrasonography was 58% compared with 83% for breast MRI; precision estimates were not reported. Specificity was 100% for both modalities.

Krammer et al (2017) published a retrospective study evaluating breast MRI to assess residual disease in 175 patients who had been candidates for BCS and had positive surgical
margins. MRIIs were read independently by 2 radiologists, both of whom had access to the pathology report from the initial surgery and any prior breast imaging. Pathology findings served as the criterion standard. For reader 1, the sensitivity and specificity of detecting residual disease was 63% and 75%, respectively. For reader 2, sensitivity and specificity were 83% and 64%, respectively. The interobserver agreement was moderate (k=0.56).

The study limitations stated in this table are those notable in the current review; this is not a comprehensive gaps assessment.

MRI: magnetic resonance imaging.

\(^a\) Selection key: 1. Selection not described; 2. Selection not random or consecutive (i.e., convenience).

\(^b\) Blinding key: 1. Not blinded to results of reference or other comparator tests.

\(^c\) Test Delivery key: 1. Timing of delivery of index or reference test not described; 2. Timing of index and comparator tests not same; 3. Procedure for interpreting tests not described; 4. Expertise of evaluators not described.

\(^e\) Data Completeness key: 1. Inadequate description of indeterminate and missing samples; 2. High number of samples excluded; 3. High loss to follow-up or missing data.

\(^f\) Statistical key: 1. Confidence intervals and/or p values not reported; 2. Comparison with other tests not reported.

**Section Summary: Evaluating Residual Tumor After Lumpectomy or Breast Conservation Surgery**

**Breast Conservation Surgery**

The available evidence is not sufficient to permit conclusions whether the use of MRI identifies the presence and/or extent of residual disease after lumpectomy or BCS and before re-excision. Most studies were retrospective, and most reported moderate sensitivity and specificity of MRI for detection of residual disease. One study published after 2015 reported the sensitivity and specificity of MRI to be over 70%. The other study published after 2015 reported a sensitivity of 83% and a specificity of 100% but offered very few details on methods, so study quality cannot be assessed.

**Summary of Evidence**

**Screening Uses**

For individuals who are asymptomatic with high-risk of breast cancer who receive MRI as an adjunct to screening for breast cancer, the evidence includes systematic reviews (including a TEC Assessment) and diagnostic accuracy studies. Relevant outcomes are overall survival (OS), disease-specific survival, test accuracy and validity, and resource utilization. Studies have found that MRI is more sensitive than mammography or ultrasonography in detecting malignancy. Because of the high likelihood of malignancy among women at high-risk for breast cancer, the benefits of detecting cancer earlier with MRI outweigh the disadvantages of incurring unnecessary workups and biopsies due to false-positive results. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who are asymptomatic with average-risk of breast cancer who receive MRI as an adjunct to screening for breast cancer, the evidence includes systematic reviews and clinical validity studies. Relevant outcomes are OS, disease-specific survival, test accuracy and validity, and resource utilization. The systematic reviews did not identify any randomized controlled trials (RCTs) or nonrandomized comparative studies evaluating MRI for screening average-risk women. One comparative observational study has been published since the systematic reviews. The diagnostic accuracy of screening tests would likely be lower in this lower prevalence population, and there would be higher false-positive rates, morbidity, and anxiety. The evidence is insufficient to determine the effects of the technology on health outcomes.

For individuals with characteristics limiting the accuracy of mammography (e.g., dense breasts) who receive MRI as an adjunct to screening for breast cancer, the evidence includes a systematic review (TEC Assessment), RCT, and diagnostic accuracy studies. Relevant outcomes are OS,
disease-specific survival, test accuracy and validity, and resource utilization. There are limited data on the diagnostic accuracy of MRI vs mammography in patients who have had breast-conserving therapy (BCT) or who have dense breasts. The evidence is insufficient to determine the effects of the technology on health outcomes.

**Detection Uses**

For individuals who have suspected occult breast primary tumor with axillary nodal adenocarcinoma with negative mammography who receive MRI as an adjunct to detect breast cancer eligible for BCT, the evidence includes a systematic review (TEC Assessment) and meta-analysis. Relevant outcomes are OS, disease-specific survival, test accuracy and validity, and resource utilization. The studies found that adjunctive use of breast MRI to guide (BCS) rather than preemptive mastectomy allowed a substantial portion of patients to avoid the morbidity of mastectomy. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have breast cancer who receive adjunctive MRI of the contralateral breast, the evidence includes cohort studies. Relevant outcomes are OS, disease-specific survival, test accuracy and validity, and resource utilization. A study of nearly 1000 patients found that MRI could detect contralateral breast cancer with a high degree of accuracy. Although long-term outcomes of these contralateral breast cancers are not fully known, important changes in management will occur (e.g., simultaneous treatment of synchronous cancers) as a result of these findings, which should lead to improved outcomes. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have low-suspicion findings on conventional mammography who receive MRI as an adjunct to detect breast cancer, the evidence includes a systematic review (TEC Assessment). Relevant outcomes are OS, disease-specific survival, test accuracy and validity, and resource utilization. The TEC Assessment concluded that, although the available studies suggested reasonably high diagnostic accuracy, none of the studies used prospective methods in appropriate study populations or appropriate comparison interventions such as short-interval mammographic follow-up. The evidence is insufficient to determine the effects of the technology on health outcomes.

For individuals who have suspicious breast lesions who receive MRI as an adjunct to further characterize lesions, the evidence includes systematic reviews (including a TEC Assessment) and cohort studies. Relevant outcomes are OS, disease-specific survival, test accuracy and validity, and resource utilization. Studies have found that MRI for evaluation of suspicious breast lesions has relatively high sensitivity and a moderately high specificity. However, it has not yet been established that the negative predictive value is sufficient to preclude the need for biopsy. Although 2 recent studies have reported negative predictive values greater than 90% in certain types of breast lesions, these were non-U.S., single-institution studies that require replication in larger, multicenter trials. Therefore, the use of MRI to further characterize suspicious lesions is currently unlikely to alter clinical management. In addition, the moderately high rate of false-positives will lead to substantial numbers of unnecessary biopsies. The evidence is insufficient to determine the effects of the technology on health outcomes.

**Treatment-Related Uses**

For individuals who have clinically localized breast cancer who receive MRI for preoperative mapping to identify multicentric disease, the evidence includes RCTs, systematic reviews, and prospective cohort studies. Relevant outcomes are OS, disease-specific survival, test accuracy and validity, and resource utilization. Studies have found that, for patients with clinically localized breast cancer, MRI can detect additional areas of disease in the ipsilateral or contralateral breast beyond that detected by standard imaging; further, MRI is associated with a higher rate of mastectomy. Follow-up studies have reported mixed results including no significant reduction in reoperation rates after MRI while other studies have reported lower odds of reoperation in patients with invasive lobular carcinoma. No significant differences in ipsilateral local or distant recurrence-
free survival after MRI-guided treatment were found in meta-analyses. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have locally advanced breast cancer undergoing neoadjuvant chemotherapy who receive an MRI to guide surgical decisions after neoadjuvant chemotherapy, the evidence includes diagnostic accuracy studies and systematic reviews. Relevant outcomes are OS, disease-specific survival, test accuracy and validity, and resource utilization. Both a 2004 TEC Assessment and a 2015 systematic review found that MRI results were well-correlated with pathologic assessment for measuring residual tumor size after neoadjuvant chemotherapy. The 2015 systematic review also found that MRI performed better than conventional methods. Using breast MRI instead of conventional methods to guide surgical decisions on BCT vs mastectomy after neoadjuvant chemotherapy would be at least as beneficial and may lead to appropriate surgical treatment more often. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have posteriorly located breast tumors who receive an MRI to diagnose chest wall involvement, the evidence includes cohort studies. Relevant outcomes are OS, disease-specific survival, test accuracy and validity, and resource utilization. Only a few small studies were identified but MRI was 100% accurate in identifying chest wall involvement compared with the criterion standard. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have a suspicious breast lesion recommended for biopsy but not localizable by mammography or ultrasonography who receive MRI to evaluate and localize the lesion prior to biopsy, the evidence includes a cohort study. Relevant outcomes are OS, disease-specific survival, test accuracy and validity, and resource utilization. A small cohort study from Brazil identified malignant tumors in 60% of patients with MRI-detected occult lesions using contrast-enhanced MRI. Although there is little published evidence supporting this indication, improved health outcomes are expected by enabling earlier diagnosis of breast cancer for suspicious lesions where other good options are not available. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have locally advanced breast cancer undergoing neoadjuvant chemotherapy who receive an MRI to evaluate response to chemotherapy, the evidence includes diagnostic accuracy studies and systematic reviews. Relevant outcomes are OS, disease-specific survival, test accuracy and validity, and resource utilization. Studies, including systematic reviews, have not found that there is sufficient evidence to determine whether breast MRI can reliably predict lack of response to neoadjuvant chemotherapy. There is a large amount of variability in reported performance characteristics of MRI in published studies, leaving uncertainty about the true accuracy of MRI for this purpose. Furthermore, evidence would need to show that any resulting change in patient management (e.g., discontinuation of chemotherapy, change to a different regimen) would improve outcomes. The evidence is insufficient to determine the effects of the technology on health outcomes.

For individuals who have positive surgical margins after lumpectomy or breast conservation surgery who receive MRI to evaluate residual tumor, the evidence includes cohort studies. Relevant outcomes are OS, disease-specific survival, test accuracy and validity, and resource utilization. The studies, most of which were retrospective and published before 2005, generally reported moderate sensitivity and specificity with MRI for detection of residual disease compared with the criterion standard. Two retrospective studies published since 2015 have an uncertain or high-risk of bias and therefore performance characteristics are unknown. The evidence is insufficient to determine the effects of the technology on health outcomes.
Supplemental Information  
Practice Guidelines and Position Statements  

National Comprehensive Cancer Network  
Current NCCN guidelines on breast cancer (v.5.2020), breast cancer screening and diagnosis (v.2.2019), and genetic assessment of those at high-risk of breast, ovarian, and pancreatic cancer (v.1.2020) list the following indications for breast magnetic resonance imaging (MRI) screening (as an adjunct to mammography):  

"Recommend Annual MRI Screening (Based on Evidence)  
• First-degree relative of BRCA carrier, but untested: Encourage genetic testing before MRI.  
• Lifetime risk 20% or greater, as defined by models that are largely dependent on family history. Encourage genetic testing for first-degree relatives. If testing declined, recommend MRI."

"Recommend Annual MRI Screening (Based on Expert Consensus Opinion):  
• Radiation to chest between 10 and 30 years"

Consider MRI screening for LCIS [lobular carcinoma in situ] and ALH [atypical lobular hyperplasia]/ADH [atypical ductal hyperplasia] based on emerging evidence if lifetime risk ≥20%  

Insufficient evidence to Recommend for or Against MRI Screening:  
• Lifetime risk 15%-20% as defined by models that are largely dependent on family history  
• Heterogeneously or extremely dense breast on mammography"

"Recommend Against MRI Screening (Based on Expert Consensus Opinion):  
• Women at <15% lifetime risk"  

The NCCN guidelines state that women at "increased risk" of breast cancer include the following groups:  

• Women with a prior history of breast cancer;  
• Women ≥ 35 years of age with a 5-year risk of invasive breast cancer ≥ 1.7% (per Modified Gail Model);  
• Women who have a lifetime risk ≥20% based on history of LCIS or ADH/ALH;  
• Women who have a lifetime risk ≥20% as defined by models that are largely dependent on family history;  
• Women who received prior thoracic irradiation between the ages of 10 and 30 years  
• Women with "a pedigree suggestive of or with a known genetic predisposition"  

The NCCN guidelines for genetic or familial high-risk assessment for breast cancer recommend MRI screening with contrast for patients with BRCA pathogenic or likely pathogenic variants starting at age 25 to 29 years or individualized if the family had breast cancer diagnosis before age 30. The guidelines further state that MRI with contrast can be considered for patients with the following genetic variants:  

• ATM, CHEK2, and NBN, starting at age 40 years  
• CDH1 and PALB2, starting at age 30 years  
• NF1, from ages 30 to 50 years  
• TP53 pathogenic/likely pathogenic variant who are treated for breast cancer and have not had a bilateral mastectomy, starting at age 20 to 29 years  
• PTEN pathogenic/likely pathogenic variant who are treated for breast cancer and have not had a bilateral mastectomy, starting at age 30 to 35 years or 5 to 10 years before the earliest breast cancer in the family  

The NCCN guidelines also state there is insufficient evidence for any recommendations for use of breast MRI for patients with the following genetic variants: BARD1, BRIP1, MLH1, MSH2, MSH6, PMS2, EPCAM, RAD51C, RAD51D, STK11, FANCC, MRE11A, MUTYH heterozygotes, RECQL4, RAD50, RINT1, SLX4, SMARCA, or XRCC2.
Guidelines on breast cancer screening and diagnosis make the following recommendations on diagnosis:\n
- Optional MRI for women with nipple discharge, no palpable mass and a BI-RADS rating of 1-3.
- Guideline discussion update in progress: “For patients with skin changes consistent with serious breast disease, consideration of breast MRI is included in the guidelines for those with benign biopsy of skin or nipple following BI-RADS category 1-3 assessment. Since a benign skin punch biopsy in a patient with clinical suspicion of inflammatory breast cancer (IBC) does not rule out malignancy, further evaluation is recommended...[and] MRI may facilitate diagnosis of IBC.”

Guidelines on breast cancer make the following recommendations on pretreatment evaluation:\n
- “May be useful for identifying primary cancer in women with axillary nodal adenocarcinoma and occult (unidentified) primary cancer, or with Paget’s disease, or with invasive lobular carcinoma poorly (or inadequately) defined on mammography, ultrasound, or physical examination.”
- "May be used for staging evaluation to define extent of cancer or presence of multifocal or multicentric cancer in the ipsilateral breast, or as screening of the contralateral breast cancer at time of initial diagnosis:"

Guidelines on breast cancer make the following recommendations on treatment:\n
- "May be helpful for breast cancer evaluation before and after preoperative systemic therapy to define extent of disease, response to treatment, and potential for breast-conserving therapy."
- “False-positive findings on breast MRI are common. Surgical decisions should not be based solely on MRI findings. Additional tissue sampling of areas of concern identified by breast MRI is recommended.”

Guidelines on breast cancer make the following recommendations on surveillance:\n
- Utility of MRI in follow-up screening in women with prior breast cancer is undefined. Generally, it should only be considered for women with a greater than 20% lifetime risk of second primary breast cancer.

**American Cancer Society**

The American Cancer Society (2017) guide on early detection of breast cancer has recommended the following on MRI:\n
- "Breast MRI is sometimes used in women who already have been diagnosed with breast cancer, to help measure the size of the cancer, look for other tumors in the breast, and to check for tumors in the opposite breast. For certain women at high-risk for breast cancer, a screening MRI is recommended along with a yearly mammogram. MRI is not recommended as a screening tool by itself because it can miss some cancers that a mammogram would find.

Although MRI can find some cancers not seen on a mammogram, it’s also more likely to find something that turns out not to be cancer (called a false positive). This can result in a woman getting tests and/or biopsies that end up not being needed. This is why MRI is not recommended as a screening test for women at average risk of breast cancer.”

**American College of Radiology**

The American College of Radiology has appropriateness criteria for breast imaging, which were developed in 2012 and revised in 2017: palpable breast masses, revised in 2016; initial workup and surveillance for stage I breast cancer, reviewed in 2019; and monitoring response to neoadjuvant therapy, 2017. (see Table 17).

MRI: magnetic resonance imaging.

The College (2018) issued recommendations for breast cancer screening in women at higher-than-average risk.63 The recommendations for MRI are as follows:
- "For women with genetics-based increased risk (and their untested first-degree relatives), history of chest radiation, calculated lifetime risk of 20% or more, breast MRI should be performed annually beginning at age 25 to 30."
- "For women with personal histories of breast cancer and dense breast tissue, or those diagnosed before age 50, annual surveillance with breast MRI is recommended."
- "For women with personal histories of breast cancer not included in the above, or with LCIS or atypia on prior biopsy, MRI should be considered, especially if other risk factors are present."

American Society of Clinical Oncology
The American Society of Clinical Oncology (2006) has published guidelines for follow-up and management after primary treatment of breast cancer.64 In 2013, the guidelines were updated with a systematic review of the literature through March 2012, and no revisions were made.65 The guidelines recommended against the use of breast MRI "for routine follow-up in an otherwise asymptomatic patient with no specific findings on clinical examination."65 Furthermore, "The decision to use breast MRI in high-risk patients should be made on an individual basis depending on the complexity of the clinical scenario."64

International Late Effects of Childhood Cancer Guideline Harmonization Group
The International Late Effects of Childhood Cancer Guideline Harmonization Group from 9 countries (2013) published evidence-based recommendations for breast cancer surveillance in female survivors of childhood, adolescent, and young adult cancer who received chest irradiation before age 30 years and have no genetic predisposition to breast cancer.66 The authors found concordance among previous guidelines to initiate annual breast MRI exams beginning at age 25 or 8 years after radiation. Based on a systematic review of the literature to August 2011 and expert consensus, the authors recommended mammography, breast MRI, or both for surveillance (strong recommendation based on high-quality evidence with a low degree of uncertainty). The authors acknowledged that "no prospective studies have assessed the use of MRI screening in this population." The recommendation was therefore based on extrapolation of evidence from patients with hereditary risk for breast cancer.
U.S. Preventive Services Task Force Recommendations
The U.S. Preventive Services Task Force (2016) updated its recommendations on breast cancer screening. The Task Force concluded the following on breast MRI:
"... the current evidence is insufficient to assess the balance of benefits and harms of adjunctive screening for breast cancer using breast ultrasonography, magnetic resonance imaging, DBT [digital breast tomosynthesis], or other methods in women identified to have dense breasts on an otherwise negative screening mammogram."

Medicare National Coverage
There is no national coverage determination. In the absence of a national coverage determination, coverage decisions are left to the discretion of local Medicare carriers.

Ongoing and Unpublished Clinical Trials
Some currently ongoing and unpublished trials that might influence this review are listed in Table 18.

**Documentation for Clinical Review**

**Please provide the following documentation:**
- History and physical and/or consultation notes including:
  - Age
  - Ethnicity/Race
  - Age at time of first live birth, if applicable
  - Age at time of first menstrual period
  - History and number of breast biopsies and pathology results
  - Diagnosis of atypical hyperplasia with at least one breast biopsy
  - History of radiation therapy and at what age, if applicable
  - Reason for MRI
  - Relatives with a history of breast cancer
- Prior genetic testing reports, if applicable (panel testing, known familial variant, etc.)
- Pathology report(s), if applicable
- Radiology report(s) (e.g., mammogram, breast ultrasound)

**Post Service (in addition to the above, please include the following):**
- Results/reports of tests performed
- Procedure report(s)

Directions of Decision Determinations

**Medically Necessary:** Services that are Medically Necessary include only those which have been established as safe and effective, are furnished under generally accepted professional standards to treat illness, injury or medical condition, and which, as determined by Blue Shield, are: (a) consistent with Blue Shield medical policy; (b) consistent with the symptoms or diagnosis; (c) not furnished primarily for the convenience of the patient, the attending Physician or other provider; (d) furnished at the most appropriate level which can be provided safely and effectively to the patient; and (e) not more costly than an alternative service or sequence of services at least as likely to produce equivalent therapeutic or diagnostic results as to the diagnosis or treatment of the Member’s illness, injury, or disease.

**Investigational/Experimental:** A treatment, procedure, or drug is investigational when it has not been recognized as safe and effective for use in treating the particular condition in accordance with generally accepted professional medical standards. This includes services where approval by the federal or state governmental is required prior to use, but has not yet been granted.

**Split Evaluation:** Blue Shield of California/Blue Shield of California Life & Health Insurance Company (Blue Shield) policy review can result in a split evaluation, where a treatment, procedure, or drug will be considered to be investigational for certain indications or conditions, but will be deemed safe and effective for other indications or conditions, and therefore potentially medically necessary in those instances.

**Prior Authorization Requirements (as applicable to your plan)**

Within five days before the actual date of service, the provider must confirm with Blue Shield that the member's health plan coverage is still in effect. Blue Shield reserves the right to revoke an authorization prior to services being rendered based on cancellation of the member's eligibility. Final determination of benefits will be made after review of the claim for limitations or exclusions.

Questions regarding the applicability of this policy should be directed to the Prior Authorization Department at (800) 541-6652, or the Transplant Case Management Department at (800) 637-2066 ext. 3507708 or visit the provider portal at www.blueshieldca.com/provider.

Disclaimer: This medical policy is a guide in evaluating the medical necessity of a particular service or treatment. Blue Shield of California may consider published peer-reviewed scientific literature, national guidelines, and local standards of practice in developing its medical policy. Federal and state law, as well as contract language, including definitions and specific contract provisions/exclusions, take precedence over medical policy and must be considered first in determining covered services. Member contracts may differ in their benefits. Blue Shield reserves the right to review and update policies as appropriate.
