Noninvasive Techniques for the Evaluation and Monitoring of Patients With Chronic Liver Disease

Policy Statement

I. A single FibroSURE multianalyte assay may be considered medically necessary once for the evaluation of individuals with chronic liver disease.

II. FibroSURE multianalyte assays are considered investigational for monitoring of individuals with chronic liver disease.

III. Other multianalyte assays with algorithmic analyses are considered investigational for the evaluation or monitoring of individuals with chronic liver disease.

IV. Transient elastography (FibroScan) imaging may be considered medically necessary once for the evaluation of individuals with chronic liver disease.

V. Transient elastography (FibroScan) imaging is considered investigational for monitoring of individuals with chronic liver disease.

VI. The use of other noninvasive imaging is considered investigational for the evaluation or monitoring of individuals with chronic liver disease including but not limited to any of the following:
   A. Magnetic resonance elastography
   B. Multiparametric magnetic resonance imaging
   C. Acoustic radiation force impulse imaging (ARFI; e.g., acuson s2000)
   D. Real-time tissue elastography

NOTE: Refer to Appendix A to see the policy statement changes (if any) from the previous version.

Policy Guidelines

Multianalyte assays with algorithmic analyses (MAAAs) use the results from multiple assays of various types in an algorithmic analysis to determine and report a numeric score(s) or probability. The results of individual component assays are not reported separately.

Coding
064 The following Category 1 CPT code replaced CPT MAAA code 0001M and is specific for the FibroSURE™ test performed by LabCorp:

- 81596: Infectious disease, chronic hepatitis C virus (HCV) infection, six biochemical assays (ALT, A2-macroglobulin, apolipoprotein A-1, total bilirubin, GGT, and haptoglobin) utilizing serum, prognostic algorithm reported as scores for fibrosis and necroinflammatory activity in liver

The following CPT multianalyte assays with algorithmic analyses (MAAA) codes are specific for the FibroSURE™ tests performed by LabCorp:

- ASH FibroSURE™, LabCorp
  - 0002M: Liver disease, ten biochemical assays (ALT, A2-macroglobulin, apolipoprotein A-1, total bilirubin, GGT, haptoglobin, AST, glucose, total cholesterol and triglycerides) utilizing serum, prognostic algorithm reported as quantitative scores for fibrosis, steatosis and alcoholic steatohepatitis (ASH)
• **NASH FibroSURE™, LabCorp**
  - **0003M**: Liver disease, ten biochemical assays (ALT, A2-macroglobulin, apolipoprotein A1, total bilirubin, GGT, haptoglobin, AST, glucose, total cholesterol and triglycerides) utilizing serum, prognostic algorithm reported as quantitative scores for fibrosis, steatosis and nonalcoholic steatohepatitis (NASH)

There is a CPT MAAA code that is specific for the Enhanced Liver Fibrosis™ (ELFTM) Test, which was produced by Siemens Healthcare Laboratory:

• **0014M**: Liver disease, analysis of 3 biomarkers (hyaluronic acid [HA], procollagen III amino terminal peptide [PIIINP], tissue inhibitor of metalloproteinase 1 [TIMP-1]), using immunoassays, utilizing serum, prognostic algorithm reported as a risk score and risk of liver fibrosis and liver-related clinical events within 5 years

**LiverFAST**

There is a CPT Proprietary Laboratory Analyses (PLA) code specific for the LiverFAST test, which was produced by Fibronostics:

• **0166U***: Liver disease, 10 biochemical assays (a2-macroglobulin, haptoglobin, apolipoprotein A1, bilirubin, GGT, ALT, AST, triglycerides, cholesterol, fasting glucose) and biometric and demographic data, utilizing serum, algorithm reported as scores for fibrosis, necroinflammatory activity, and steatosis with a summary interpretation

*Note: This test is for adult individuals with non-alcoholic fatty liver disease from asymptomatic early stage through non-malignant late stage. The test utilizes a combination of serum biomarkers and patient demographics that is intended to aid in the staging of fibrosis, inflammatory activity, and steatosis of liver disease. This test is not intended for use as a stand-alone test, but to be used in conjunction with other laboratory, radiological and clinical findings.

**FIBROSpect**

There are no specific CPT codes that represent FIBROSpect as a whole. At this time, it may be reported using the unlisted chemistry procedure code 84999, or with the codes for each component test. There is no specific CPT code for the use of the associated proprietary algorithm for FIBROSpect. The following CPT codes are examples of possible coding:

• **Hyaluronic acid**
  - **83520**: Immunoassay for analyte other than infectious agent antibody or infectious agent antigen; quantitative, not otherwise specified

• **Tissue inhibitor of metalloproteinase (TIMP-1)**
  - **83520**: Immunoassay for analyte other than infectious agent antibody or infectious agent antigen; quantitative, not otherwise specified

• **Alpha-2-macroglobulin**
  - **83883**: Nephelometry, each analyte not elsewhere specified

**Elastography**

The following CPT code is specific for liver elastography without imaging:

• **91200**: Liver elastography, mechanically induced shear wave (e.g., vibration), without imaging, with interpretation and report

The following CPT codes that specifically describe ultrasound elastography will replace category III CPT code 0346T and will be used in conjunction with other ultrasound tests:

• **76981**: Ultrasound, elastography; parenchyma (e.g., organ). This code is for the entire organ
• **76982**: Ultrasound, elastography; first target lesion
• **76983**: Ultrasound, elastography; each additional target lesion (List separately in addition to code for primary procedure). This code an add-on to the primary procedure 76982
The following CPT code may be billed for Magnetic Resonance Elastography (MRE):

- **76391**: Magnetic resonance (e.g., vibration) elastography

This policy does not address standard imaging with ultrasound or magnetic resonance imaging.

There are two Category III codes that were created for reporting quantitative magnetic resonance for analysis of tissue composition. Per the manufacturer, this technology uses software to analyze tissue physiology (most commonly in chronic liver disease) and generates diagnostic information, (i.e., parametric maps and summary statistics):

- **0648T**: Quantitative magnetic resonance for analysis of tissue composition (e.g., fat, iron, water content), including multiparametric data acquisition, data preparation and transmission, interpretation and report, obtained without diagnostic MRI examination of the same anatomy (e.g., organ, gland, tissue, target structure) during the same session; single organ
- **0649T**: Quantitative magnetic resonance for analysis of tissue composition (e.g., fat, iron, water content), including multiparametric data acquisition, data preparation and transmission, interpretation and report, obtained with diagnostic MRI examination of the same anatomy (e.g., organ, gland, tissue, target structure); single organ (List separately in addition to code for primary procedure)

### Description

Noninvasive techniques to monitor liver fibrosis are being investigated as alternatives to liver biopsy in patients with chronic liver disease. There are 2 options for noninvasive monitoring: (1) multianalyte serum assays with algorithmic analysis of either direct or indirect biomarkers; and (2) specialized radiologic methods, including magnetic resonance elastography, multiparametric magnetic resonance imaging (MRI), transient elastography, acoustic radiation force impulse imaging, and real-time transient elastography.

### Related Policies

### Benefit Application

Benefit determinations should be based in all cases on the applicable contract language. To the extent there are any conflicts between these guidelines and the contract language, the contract language will control. Please refer to the member’s contract benefits in effect at the time of service to determine coverage or non-coverage of these services as it applies to an individual member.

Some state or federal mandates (e.g., Federal Employee Program [FEP]) prohibits plans from denying Food and Drug Administration (FDA)-approved technologies as investigational. In these instances, plans may have to consider the coverage eligibility of FDA-approved technologies on the basis of medical necessity alone.

### Regulatory Status

In 2008 Acuson S2000™ Virtual Touch (Siemens AG), which provides ARFI imaging, was cleared for marketing by the U.S. Food and Drug Administration (FDA) through the 510(k) process (K072786).

In 2009, AIXPLORER® Ultrasound System (SuperSonic Imagine), which provides shear wave elastography, was cleared for marketing by the FDA through the 510(k) process (K091970).
In 2010, Hitachi HI VISION™ Preirus™ Diagnostic Ultrasound Scantier (Hitachi Medical Systems America), which provides real-time tissue elastography, was cleared for marketing by the FDA through the 510(k) process (K093466).

In 2013, FibroScan® (EchoSens), which uses transient elastography, was cleared for marketing by the FDA through the 510(k) process (K123806).

In June 2015, LiverMultiScan (Perspectum), which is a magnetic resonance diagnostic device software application, was cleared for marketing by the FDA through the 510(k) process (K143020).

In February 2017, ElastQ Imaging shear wave elastography (Royal Phillips) was cleared for marketing by the FDA through the 510(k) process (K163120).

In August 2021, ADVIA Centaur ELFTM test (Siemens Healthcare) was cleared for marketing by the FDA through the 513(f)(2) De Novo review pathway (DENI90056). In 2018, the device had been granted a Breakthrough Device designation.

FDA product codes: IYO, LNH, QQB.

Rationale

Background
Biopsy for Chronic Liver Disease
The diagnosis of non-neoplastic liver disease is often made from needle biopsy samples. In addition to establishing a disease etiology, liver biopsy can determine the degree of inflammation present and stage the degree of fibrosis. The degree of inflammation and fibrosis may be assessed by different scoring schemes. Most of these scoring schemes grade inflammation from 0 (no or minimal inflammation) to 4 (severe) and fibrosis from 0 (no fibrosis) to 4 (cirrhosis). There are several limitations to liver biopsy, including its invasive nature, small tissue sample size, and subjective grading system. Regarding small tissue sample size, liver fibrosis can be patchy and thus missed on a biopsy sample, which includes only 0.002% of the liver tissue. A noninvasive alternative to liver biopsy would be particularly helpful, both to initially assess patients and then to monitor response to therapy. The implications of using liver biopsy as a reference standard are discussed in the Rationale.

Hepatitis C Virus
Infection with hepatitis C virus (HCV) can lead to permanent liver damage. Prior to noninvasive testing, liver biopsy was typically recommended before the initiation of antiviral therapy. Repeat biopsies may be performed to monitor fibrosis progression. Liver biopsies are analyzed according to a histologic scoring system; the most commonly used one for HCV is the Metavir system, which scores the presence and degree of inflammatory activity and fibrosis. The fibrosis is graded from F0 to F4, with a Metavir score of F0 signifying no fibrosis and F4 signifying cirrhosis (which is defined as the presence throughout the liver of fibrous septa that subdivide the liver parenchyma into nodules, representing the final and irreversible form of the disease). The stage of fibrosis is the most important single predictor of morbidity and mortality in patients with hepatitis C. Biopsies for HCV are also evaluated according to the degree of inflammation present, referred to as the grade or activity level. For example, the Metavir system includes scores for necroinflammatory activity ranging from A0 to A3 (A0 = no activity, A1 = minimal activity, A2 = moderate activity, A3 = severe activity).

Hepatitis B Virus
Most people who become infected with hepatitis B virus (HBV) recover fully, but a small portion develops chronic HBV, which can lead to permanent liver damage. As with HCV, identification of liver
fibrosis is needed to determine timing and management of treatment, and liver biopsy is the criterion standard for staging fibrosis. The grading of fibrosis in HBV also uses the Metavir system.

**Alcoholic Liver Disease**
Alcoholic liver disease (ALD) is the leading cause of liver disease in most Western countries. Histologic features of ALD usually include steatosis, alcoholic steatohepatitis (ASH), hepatocyte necrosis, Mallory bodies (tangled proteins seen in degenerating hepatocytes), a large polymorphonuclear inflammatory infiltrate, and, with continued alcohol abuse, fibrosis, and possibly cirrhosis. The grading of fibrosis is similar to the scoring system used in HCV. The commonly used Laënnec scoring system uses grades 0 to 4, with 4 being cirrhosis.

**Nonalcoholic Fatty Liver Disease**
Nonalcoholic fatty liver disease (NAFLD) is defined as a condition that pathologically resembles ALD, but occurs in patients who are not heavy users of alcohol. Moreover, NAFLD may be associated with a variety of conditions, including obesity, diabetes, and dyslipidemia. The characteristic feature of NAFLD is steatosis. At the benign end of the disease spectrum, there is usually no appreciable inflammation, hepatocyte death, or fibrosis. In contrast, nonalcoholic steatohepatitis (NASH), which shows overlapping histologic features with ALD, is an intermediate form of liver damage, and liver biopsy may show steatosis, Mallory bodies, focal inflammation, and degenerating hepatocytes. NASH can progress to fibrosis and cirrhosis. A variety of histologic scoring systems have been used to evaluate NAFLD. The NAFLD Activity Score system for NASH includes scores for steatosis (0 to 3), lobular inflammation (0 to 3), and ballooning (0 to 2). Cases with scores of 5 or greater are considered NASH, while cases with scores of 3 and 4 are considered borderline (probable or possible) NASH. The grading of fibrosis is similar to the scoring system used in hepatitis C. The commonly used Laënnec scoring system uses grades 0 to 4, with 4 being cirrhosis.

**Noninvasive Alternatives to Liver Biopsy**

**Multianalyte Assays**
A variety of noninvasive laboratory tests are being evaluated as alternatives to liver biopsy. Biochemical tests can be broadly categorized into indirect and direct markers of liver fibrosis. Indirect markers include liver function tests such as alanine aminotransferase (ALT), aspartate aminotransferase (AST), the ALT/AST ratio (also referred to as the AAR), platelet count, and prothrombin index. There has been a growing understanding of the underlying pathophysiology of fibrosis, leading to a direct measurement of the factors involved. For example, the central event in the pathophysiology of fibrosis is the activation of the hepatic stellate cell. Normally, stellate cells are quiescent, but are activated in the setting of liver injury, producing a variety of extracellular matrix (ECM) proteins. In normal livers, the rate of ECM production equals its degradation, but with fibrosis, production exceeds degradation. Metalloproteinases are involved in intracellular degradation of ECM, and a profibrogenic state exists when there is either a down-regulation of metalloproteinases or an increase in tissue inhibitors of metalloproteinases. Both metalloproteinases and tissue inhibitors of metalloproteinases can be measured in the serum, which directly reflects the fibrotic activity. Other direct measures of ECM deposition include hyaluronic acid or \( \alpha_2 \)-macroglobulin.

While many studies have been done on these individual markers, or on groups of markers in different populations of patients with liver disease, there has been interest in analyzing multiple markers using mathematical algorithms to generate a score that categorizes patients according to the biopsy score. It is proposed that these algorithms can be used as alternatives to liver biopsy in patients with liver disease. The following proprietary, algorithm-based tests are commercially available in the U.S.

There are 3 different FibroSURE tests available depending on the indication for use: HCV FibroSURE, ASH FibroSURE, and NASH FibroSURE.
HCV FibroSURE
The HCV FibroSURE uses a combination of 6 serum biochemical indirect markers of liver function plus age and sex in a patented algorithm to generate a measure of fibrosis and necroinflammatory activity in the liver that corresponds to the Metavir scoring system for stage (i.e., fibrosis) and grade (i.e., necroinflammatory activity). The measures are combined using a linear regression equation to produce a score between 0 and 1, with higher values corresponding to more severe disease. The biochemical markers include the readily available measurements of $\alpha_2$-macroglobulin, haptoglobin, bilirubin, $\gamma$-glutamyl transpeptidase, ALT, and apolipoprotein AI. Developed in France, the test has been clinically available in Europe under the name FibroTest since 2003; it is exclusively offered by LabCorp in the U.S. as HCV FibroSURE.

ASH FibroSURE
ASH FibroSURE (ASH Test) uses a combination of 10 serum biochemical markers of liver function together with age, sex, height, and weight in a proprietary algorithm; the test is proposed to provide surrogate markers for liver fibrosis, hepatic steatosis, and ASH. The biochemical markers include $\alpha_2$-macroglobulin, haptoglobin, apolipoprotein AI, bilirubin, $\gamma$-glutamyl transpeptidase, ALT, AST, total cholesterol, triglycerides, and fasting glucose. The test has been available in Europe under the name AshTest™ (BioPredictive); the test is exclusively offered by LabCorp in the U.S. as ASH FibroSURE.

NASH FibroSURE
NASH FibroSURE (NASH Test) uses a proprietary algorithm of the same 10 biochemical markers of liver function in combination with age, sex, height, and weight and is proposed to provide surrogate markers for liver fibrosis, hepatic steatosis, and NASH. The biochemical markers include $\alpha_2$-macroglobulin, haptoglobin, apolipoprotein AI, bilirubin, $\gamma$-glutamyl transpeptidase, ALT, AST, total cholesterol, triglycerides, and fasting glucose. The test has been available in Europe under the name NashTest™ (BioPredictive); the test is exclusively offered by LabCorp in the U.S. as NASH FibroSURE.

FIBROSpect II
FIBROSpect II uses a combination of 3 markers that directly measure fibrogenesis of the liver, analyzed with a patented algorithm. The markers include hyaluronic acid, tissue inhibitor of metalloproteinase 1, and $\alpha_2$-macroglobulin. FIBROSpect II is offered exclusively by Prometheus Laboratories. The measures are combined using a logistic regression algorithm to generate a FIBROSpect II index score, ranging from 1 to 100 (or sometimes reported between 0 and 1), with higher scores indicating more severe disease.

Enhanced Liver Fibrosis Test
The Enhanced Liver Fibrosis (ELF) test uses a proprietary algorithm to produce a score based on 3 serum biomarkers involved in matrix biology: hyaluronic acid, Procollagen III amino terminal peptide and tissue inhibitor of metalloproteinase 1. The manufacturer recommends the following cutoffs for interpretation for risk of development of cirrhosis or liver-related events in patients with NASH: <9.80 (lower risk) and ≥11.30 (higher risk).

Noninvasive Imaging Technologies
Noninvasive imaging technologies to detect liver fibrosis or cirrhosis among patients with chronic liver disease are being evaluated as alternatives to liver biopsy. The noninvasive imaging technologies include transient elastography (e.g., FibroScan), magnetic resonance elastography, acoustic radiation force impulse (ARFI) imaging (e.g., Acuson S2000), multiparametric magnetic resonance imaging (MRI), and real-time tissue elastography (e.g., HI VISION Preirus). Noninvasive imaging tests have been used in combination with multianalyte serum tests such as FibroTest or FibroSURE with FibroScan.

Transient Elastography
Transient elastography (FibroScan) uses a mechanical vibrator to produce mild amplitude and low-frequency (50 Hz) waves, inducing an elastic shear wave that propagates throughout the liver.
Ultrasound tracks the wave, measuring its speed in kilopascals, which correlates with liver stiffness. Increases in liver fibrosis also increase liver stiffness and resistance of liver blood flow. Transient elastography does not perform as well in patients with ascites, higher body mass index, or narrow intercostal margins. Although FibroScan may be used to measure fibrosis (unlike liver biopsy), it does not provide information on necroinflammatory activity and steatosis, nor is it accurate during acute hepatitis or hepatitis exacerbations.

**Acoustic Radiation Force Impulse Imaging**
ARFI imaging uses an ultrasound probe to produce an acoustic “push” pulse, which generates shear waves that propagate in tissue to assess liver stiffness. ARFI elastography evaluates the wave propagation speed (measured in meters per second) to assess liver stiffness. The faster the shear wave speed, the harder the object. ARFI technologies include Virtual Touch Quantification and Siemens Acuson S2000 system. ARFI elastography can be performed at the same time as a liver sonographic evaluation, even in patients with a significant amount of ascites.

**Magnetic Resonance Elastography**
Magnetic resonance elastography uses a driver to generate 60-Hz mechanical waves on the patient’s chest wall. The magnetic resonance equipment creates elastograms by processing the acquired images of propagating shear waves in the liver using an inversion algorithm. These elastograms represent the shear stiffness as a pixel value in kilopascals. Magnetic resonance elastography has several advantages over ultrasound elastography, including: (1) the ability to analyze larger liver volumes; (2) the ability to analyze liver volumes of obese patients or patients with ascites; and (3) the ability to precisely analyze viscoelasticity using a 3-dimensional displacement vector.

**Real-Time Tissue Elastography**
Real-time tissue elastography is a type of strain elastography that uses a combined autocorrelation method to measure tissue strain caused by manual compression or a person’s heartbeat. The relative tissue strain is displayed on conventional color B mode ultrasound images in real-time. Hitachi manufactures real-time tissue elastography devices, including the HI VISION Preirus. The challenge is to identify a region of interest while avoiding areas likely to introduce artifacts, such as large blood vessels, the area near the ribs, and the surface of the liver. Areas of low strain increase as fibrosis progresses and strain distribution becomes more complex. Various subjective and quantitative methods have been developed to evaluate the results. Real-time tissue elastography can be performed in patients with ascites or inflammation. This technology does not perform as well in severely obese individuals.

**Multiparametric Magnetic Resonance Imaging**
Multiparametric MRI combines proton density fat-fraction, T2*, and T1 mapping. Proton density fat-fraction provides an assessment of hepatic fat content and can be used to determine the grade of liver steatosis. T1 relaxation times are used to assess increases in extracellular fluid, which correlates with the extent of fibrosis and inflammation of the liver. Hepatic iron quantification is measured through T2* relaxation times as T1 relaxation times are decreased by excess iron in the liver tissue. LiverMultiScan® uses a clinical algorithm that accounts for an iron-corrected T1 value, based on the T2* relaxation time, and proton density fat-fraction to assess the presence of fat, inflammation, and fibrosis.

**Literature Review**
Evidence reviews assess whether a medical test is clinically useful. A useful test provides information to make a clinical management decision that improves the net health outcome. That is, the balance of benefits and harms is better when the test is used to manage the condition than when another test or no test is used to manage the condition.
The first step in assessing a medical test is to formulate the clinical context and purpose of the test. The test must be technically reliable, clinically valid, and clinically useful for that purpose. Evidence reviews assess the evidence on whether a test is clinically valid and clinically useful. Technical reliability is outside the scope of these reviews, and credible information on technical reliability is available from other sources.

Noninvasive Testing for Chronic Liver Disease

Liver biopsy is an imperfect reference standard. There is a high rate of sampling error, which can lead to underdiagnosis of liver disease.\(^1\,\(^2\) These errors will bias estimates of performance characteristics of the noninvasive tests to which it is compared, and therefore such errors must be considered in appraising the body of evidence. Mehta et al (2009) estimated that even under the best scenario where sensitivity and specificity of liver biopsy are 90%, and the prevalence of significant disease (increased liver fibrosis, scored as Metavir ≥F2) is 40%; a perfect alternative marker would have calculated the area under the receiver operating characteristic (AUROC) curve of 0.90.\(^3\) Therefore, the effectiveness of alternative technologies may be underestimated. In fact, when the accuracy of biopsy is presumed to be 80%, a comparative technology with an AUROC curve of 0.76 may actually have an AUROC curve of 0.93 to 0.99 for diagnosing true disease.

Due to a large number of primary studies published on this topic, this evidence review focuses on systematic reviews when available. The validation of multiple noninvasive tests is assessed individually in the following sections. Although options exist for performing systematic reviews with imperfect reference standards,\(^4\) most available reviews did not use any correction for the imperfect reference.

A systematic review by Crossan et al (2015) was performed for the National Institute for Health Research.\(^5\) The first objective of the review was to determine the diagnostic accuracy of different noninvasive liver tests compared with liver biopsy in the diagnosis and monitoring of liver fibrosis and cirrhosis in patients with hepatitis C virus (HCV), hepatitis B virus (HBV), nonalcoholic fatty liver disease (NAFLD), and alcoholic liver disease (ALD). Reviewers selected 302 publications and presentations from 1998 to April 2012. Patients with HCV were the most common population included in the studies while patients with ALD were the least common. FibroScan and FibroTest were the most commonly assessed tests across liver diseases. Aminotransferase to platelet ratio index (APRI) was also widely assessed in HBV and HCV but not in NAFLD or ALD. The estimates of diagnostic accuracy for each test by disease are discussed in further detail in the following sections. Briefly, for diagnosing significant fibrosis (stage ≥F2) in HCV, the summary sensitivities and specificities were: FibroScan, 79% and 83%; FibroTest, 68% and 72%; APRI (low cutoff), 82% and 57%; acoustic radiation force impulse (ARFI) imaging, 85% and 89%; HepaScore, 73% and 73%; FIBROSpect II, 78% and 71%; and Fibrometer, 79% and 73%, respectively. For diagnosing advanced fibrosis in HBV, the summary sensitivities and specificities were: FibroScan, 71% and 84%; and FibroTest, 66% and 80%, respectively. There are no established or validated cutoffs for fibrosis stages across the diseases for most tests. For FibroTest, established cutoffs exist, but were used inconsistently across studies. Test failures or reference standard(s) were frequently not captured in analyses. Most populations included in the studies were from tertiary care settings that have more advanced disease than the general population, which would overestimate the prevalence of the disease and diagnostic accuracy. These issues likely cause overestimates of sensitivities and specificities. The quality of the studies was generally rated as poor, with only 1.6% receiving a high-quality rating.

Houot et al (2016) reported on a systematic review funded by BioPredictive, the manufacturer of FibroTest.\(^6\) This review included 71 studies published between January 2002 to February 2014 with over 12,000 participants with HCV and HBV comparing the diagnostic accuracy of FibroTest, FibroScan, APRI, and fibrosis-4 (FIB-4) index. Included studies directly compared the tests and calculated median differences in the AUROC curve using Bayesian methods. There was no evaluation of the methodologic quality of the included studies. The Bayesian difference in AUROC curve for significant fibrosis (stage ≥F2) between FibroTest and FibroScan was based on 15 studies and
estimated to be 0.06 (95% credible interval [CrI], 0.02 to 0.09) favoring FibroTest. The difference in AUROC curve for cirrhosis for FibroTest versus FibroScan was based on 13 studies and estimated to be 0.00 (95% CrI, -0.04 to 0.04). The difference for advanced fibrosis between FibroTest and APRI was based on 21 studies and estimated to be 0.05 (95% CrI, 0.03 to 0.07); for cirrhosis, it was based on 14 studies and estimated to be 0.05 (95% CrI, 0.00 to 0.11), both favoring FibroTest.

FibroSURE Serum Panel
Clinical Context and Test Purpose
The purpose of noninvasive testing in individuals with chronic liver disease is to detect liver fibrosis so that patients can avoid the potential adverse events of an invasive liver biopsy and receive appropriate treatment. The degree of liver fibrosis is an important factor in determining the appropriate approach for managing patients with liver disease (e.g., hepatitis, ALD, NAFLD).

The question addressed in this portion of the evidence review is: Does the use of the FibroSURE multianalyte serum assay for detecting liver fibrosis improve the net health outcome in patients with chronic liver disease?

The following PICO was used to select literature to inform this review.

Populations
The relevant population of interest is individuals with chronic liver disease.

Interventions
The test being considered is the FibroSURE serum panel.

Comparators
The following tests and practices are currently being used to diagnose chronic liver disease: liver biopsy, noninvasive radiologic methods, and other multianalyte serum assays.

Outcomes
The general outcomes of interest are test validity, morbid events, and treatment-related morbidity. Follow-up over months to years is of interest to the relevant outcomes.

Study Selection Criteria
For the evaluation of the clinical validity of the tests within this review, studies that meet the following eligibility criteria were considered:

- Reported on the accuracy of the marketed version of the technology (including any algorithms used to calculate scores).
- Included a suitable reference standard (describe the reference standard).
- Patient/sample clinical characteristics were described.
- Patient/sample selection criteria were described.

Hepatitis C Virus
Clinically Valid
A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

Review of Evidence
Following the initial research into FibroSURE (patients with liver fibrosis who had undergone biopsy)⁷, the next step in the development of this test was a further evaluation of the algorithm in a cross-section of patients, including patients with HCV participating in large clinical trials before and after the initiation of antiviral therapy. A study by Poynard et al (2003) focused on patients with HCV participating in a randomized study of pegylated interferon and ribavirin.⁸ From the 1530 participants, 352 patients with stored serum samples and liver biopsies at study entry and at 24-week
follow-up were selected. The HCV FibroSURE score was calculated and then compared with the
Metavir liver biopsy score. At a cutoff of 0.30, the HCV FibroSURE score had 90% sensitivity and 88%
positive predictive value (PPV) for the diagnosis of Metavir F2 to F4 fibrosis; the specificity was 36%,
and the negative predictive value (NPV) was 40%.

Poynard et al (2004) also evaluated discordant results in 537 patients who underwent liver biopsy
and the HCV FibroSURE and ActiTest on the same day; discordance was attributed to either the
limitations in the biopsy or serum markers.9 In this study, cutoff values were used for individual
Metavir scores (i.e., F0 to F4) and for combinations of Metavir scores (i.e., F0 to F1, F1 to F2). The
definition of a significant discordance between FibroTest and ActiTest and biopsy scores was at least
2 stages or grades in the Metavir system. Discordance was observed in 29% of patients. Risk factors
for failure of the HCV FibroSURE scoring system were as follows: the presence of hemolysis,
inflammation, possible Gilbert syndrome, acute hepatitis, drugs inducing cholestasis, or an increase in
transaminases. Discordance was attributable to markers in 2.4% of patients, to the biopsy in 18%,
and unattributed in 8.2% of patients. As noted in 2 reviews, the bulk of the research on HCV
FibroSURE was conducted by researchers with an interest in the commercialization of the
algorithm.10,11

In the Crossan et al (2015) systematic review, FibroTest was the most widely validated commercial
serum test.5 Seventeen studies were included in the pooled estimate of the diagnostic accuracy of
FibroTest for significant fibrosis (stage ≥F2) in HCV. With varying cutoffs for positivity between 0.32
and 0.53, the summary sensitivity in HCV was 68% (95% confidence interval [CI], 58% to 77%) and
specificity was 72% (95% CI, 70% to 77%). Eight studies were included for cirrhosis (stage F4) in HCV.
The cutoffs for positivity ranged from 0.56 to 0.74 and the summary sensitivity and specificity were
60% (95% CI, 45% to 76%) and 86% (95% CI, 81% to 91%), respectively. Uninterpretable results were
rare for tests based on serum markers.

Clinically Useful
A test is clinically useful if the use of the results informs management decisions that improve the net
health outcome of care. The net health outcome can be improved if patients receive correct therapy,
more effective therapy, or avoid unnecessary therapy or testing.

Direct Evidence
Direct evidence of clinical utility is provided by studies that have compared health outcomes for
patients managed with and without the test. Because these are intervention studies, the preferred
evidence would be from randomized controlled trials (RCTs). The primary benefit of the FibroSURE
(FibroTest in Europe) for HCV is the ability to avoid liver biopsy in patients without significant fibrosis.
There are currently no such published studies to demonstrate the effect on patient outcomes.

The FibroSURE test also has a potential effect on patient outcomes as a means to follow response to
therapy. In this case, evidence needs to demonstrate that the use of the test for response to therapy
impacts decision making and that these changes in management decisions lead to improved
outcomes. It is not clear whether HCV FibroSURE could be used as an interval test in patients receiving therapy to determine whether an additional liver biopsy is necessary.

Chain of Evidence
Indirect evidence on clinical utility rests on clinical validity. If the evidence is insufficient to demonstrate test performance, no inferences can be made about clinical utility.

Alcoholic Liver Disease and Alcoholic Steatohepatitis
Clinically Valid
A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

Review of Evidence
The diagnostic value of FibroSURE (FibroTest in Europe) has also been evaluated for the prediction of liver fibrosis in patients with ALD and NAFLD. Thabut et al (2006) reported the development of a panel of biomarkers (ASH FibroSURE [ASH Test]) for the diagnosis of alcoholic steatohepatitis (ASH) in patients with chronic ALD. Biomarkers were initially assessed in a training group of 70 patients, and a panel was constructed using a combination of the 6 biochemical components of the FibroTest-ActiTest plus aspartate aminotransferase (AST). The algorithm was subsequently studied in 2 validation groups (1 prospective study for severe ALD, 1 retrospective study for nonsevere ALD) that included 155 patients and 299 controls. The severity of ASH (none, mild, moderate, severe) was blindly assessed from biopsy samples. In the validation groups, there were 28 (18%) cases of discordance between the diagnosis of ASH predicted by the ASH Test and biopsy; 10 (36%) were considered false-negatives of the ASH Test, and 11 were suspected failures of biopsy. Seven cases were indeterminate by biopsy. The AUROC curves were 0.88 and 0.89 in the validation groups. The median ASH Test value was 0.005 in controls, 0.05 in patients without or with mild ASH, 0.64 in the moderate ASH grade, and 0.84 in severe ASH grade 3. Using a cutoff value of 0.50, the ASH Test had a sensitivity of 80% and specificity of 84%, with PPVs and NPVs of 72% and 89%, respectively.

Several authors had an interest in the commercialization of this test, and no independent studies on the diagnostic accuracy of ASH FibroSURE (ASH Test) were identified. In addition, it is not clear if the algorithm used in this study is the same as that used in the currently commercially available test, which includes 10 biochemicals.

FibroTest has been studied in patients with ALD. In the Crossan et al (2015) systematic review, 1 study described the diagnostic accuracy of the FibroTest for significant fibrosis (stage ≥ F2) or cirrhosis in ALD. With a high cutoff for positivity (0.7), the sensitivity and specificity for advanced fibrosis were 55% (95% CI, 47% to 63%) and 93% (95% CI, 85% to 97%) and for cirrhosis were 91% (95% CI, 82% to 96%) and 87% (95% CI, 81% to 91%), respectively. With a low cutoff for positivity (0.3), the sensitivity and specificity for advanced fibrosis were 84% (95% CI, 77% to 89%) and 65% (95% CI, 55% to 75%), respectively. The sensitivity and specificity for cirrhosis were 100% (95% CI, 95% to 100%) and 50% (95% CI, 42% to 58%), respectively.

Clinically Useful
A test is clinically useful if the use of the results informs management decisions that improve the net health outcome of care. The net health outcome can be improved if patients receive correct therapy, more effective therapy, or avoid unnecessary therapy or testing.

Direct Evidence
Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. Because these are intervention studies, the preferred evidence would be from RCTs.
No studies were identified that assessed clinical outcomes following the use of the ASH FibroSURE (ASH Test) in ALD and ASH.

**Chain of Evidence**
Indirect evidence on clinical utility rests on clinical validity. If the evidence is insufficient to demonstrate test performance, no inferences can be made about clinical utility.

**Nonalcoholic Fatty Liver Disease and Nonalcoholic Steatohepatitis**
Clinically Valid
A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

**Review of Evidence**
Poynard et al (2006) reported the development of a panel of biomarkers (NASH FibroSURE [NASH Test]) for the prediction of nonalcoholic steatohepatitis (NASH) in patients with NAFLD.\(^2\) Biomarkers were initially assessed with a training group of 160 patients, and a panel was constructed using a combination of 13 of 14 parameters of the currently available test. The algorithm was subsequently studied in a validation group of 97 patients and 383 controls. Patients in the validation group were from a prospective multicenter study with hepatic steatosis at biopsy and suspicion of NAFLD. Histologic diagnoses used Kleiner et al's scoring system, with 3 classes for NASH (NASH, borderline NASH, no NASH). The main endpoint was steatohepatitis, defined as a histologic NASH score of 5 or greater. The AUROC curve for the validation group was 0.79 for the diagnosis of NASH, 0.69 for the diagnosis of borderline NASH, and 0.83 for the diagnosis of no NASH. Results showed a sensitivity of 33% and specificity of 94% for NASH, with a PPV and NPV of 66% and 81%, respectively. For borderline NASH or NASH, sensitivity was 88%, specificity 50%, PPV 74%, and NPV 72%. Clinically significant discordance (2 class difference) was observed in 8 (8%) patients. None of the 383 controls were considered to have NASH by NASH FibroSURE (NASH Test). Authors proposed that this test would be suitable for mass screening for NAFLD in patients with obesity and diabetes.

An independent study by Lassailly et al (2011) attempted to prospectively validate the NASH Test (along with the FibroTest, SteatoTest, and ActiTest) in a cohort of 288 patients treated with bariatric surgery.\(^2\) Included were patients with severe or morbid obesity (body mass index, >35 kg/m\(^2\)), at least 1 comorbidity for at least 5 years, and resistance to medical treatment. Excluded were patients with current excessive drinking, long-term consumption of hepatotoxic drugs, and positive screening for chronic liver diseases including hepatitis. Histology and biochemical measurements were centralized and blinded to other characteristics. The NASH Test provided a 3-category score for no NASH (0.25), possible NASH (0.50), and NASH (0.75). The prevalence of NASH was 6.9%, while the prevalence of NASH or possible NASH was 27%. The concordance rate between the histologic NASH score and the NASH Test was 43.1%, with a weak \(\kappa\) reliability test (0.14). In 183 patients categorized as possible NASH by the NASH Test, 124 (68%) were classified as no NASH by biopsy. In 15 patients categorized as NASH by the NASH Test, 7 (47%) were no NASH and 4 (27%) were possible NASH by biopsy. The NPV of the NASH Test for possible NASH or NASH was 47.5%. Authors suggested that the power of this study to validate agreement between the NASH Test and biopsy was low, due to the low prevalence of NASH. However, the results showed poor concordance between the NASH Test and biopsy, particularly for intermediate values.

In the Crossan et al (2015) systematic review, 4 studies were included in the pooled estimate of the diagnostic accuracy of FibroTest for advanced fibrosis (stage \(\geq 3\)) in NAFLD.\(^3\) The summary sensitivities and specificities were 40% (95% CI, 24% to 58%) and 96% (95% CI, 91% to 98%), respectively. Only 1 study included reported accuracy for cirrhosis, with sensitivity and specificity of 74% (95% CI, 54%, to 87%) and 92% (95% CI, 88% to 95%), respectively.
Clinically Useful
A test is clinically useful if the use of the results informs management decisions that improve the net health outcome of care. The net health outcome can be improved if patients receive correct therapy, more effective therapy, or avoid unnecessary therapy or testing.

Direct Evidence
Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. Because these are intervention studies, the preferred evidence would be from RCTs.

No studies were identified that assessed clinical outcomes following the use of the NASH FibroSURE (NASH Test) in NAFLD and NASH.

Chain of Evidence
Indirect evidence on clinical utility rests on clinical validity. If the evidence is insufficient to demonstrate test performance, no inferences can be made about clinical utility.

Hepatitis B Virus
Clinically Valid
A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

Review of Evidence
While most multianalyte assay studies that have identified fibrosis have been conducted in patients with HCV, studies are also being conducted in patients with chronic HBV. In a study, Park et al (2013) compared liver biopsy with the FibroTest results obtained on the same day from 330 patients who had chronic HBV. Discordance was found in 30 (9.1%) patients for whom the FibroTest underestimated fibrosis in 25 patients and overestimated it in 5 patients. Those with Metavir liver fibrosis stage F3 or F4 (15.4%) had a significantly higher discordance rate than those with stages F1 or F2 (3.0%; p<.001). The only independent factor for discordance on multivariate analysis was a Metavir stage F3 or F4 on liver biopsy (p<.001).

Salkic et al (2014) conducted a meta-analysis of studies on the diagnostic accuracy of FibroTest in chronic HBV. Included in the meta-analysis were 16 studies (n=2494) on liver fibrosis diagnosis and 13 studies (n=1754) on cirrhosis diagnosis. There was strong evidence of heterogeneity in the 16 fibrosis studies and evidence of heterogeneity in the cirrhosis studies. For significant liver fibrosis (Metavir F2 to F4) diagnosis using all of the fibrosis studies, the AUROC curve was 0.84 (95% CI, 0.78 to 0.88). At the recommended FibroTest threshold of 0.48 for a significant liver fibrosis diagnosis, the sensitivity was 60.9%, specificity was 79.9%, and the diagnostic odds ratio (OR) was 6.2. For liver cirrhosis (Metavir F4) diagnosis using all of the cirrhosis studies, the AUROC curve was 0.87 (95% CI, 0.85 to 0.9). At the recommended FibroTest threshold of 0.74 for cirrhosis diagnosis, the sensitivity was 61.5%, specificity was 90.8%, and the diagnostic OR was 15.7. While the results demonstrated FibroTest may be useful in excluding a diagnosis of cirrhosis in patients with chronic HBV, the ability to detect significant fibrosis and cirrhosis and exclude significant fibrosis is suboptimal.

Xu et al (2014) reported on a systematic review and meta-analysis of studies assessing biomarkers to detect fibrosis in HBV. Included in the analysis of FibroTest were 11 studies (N=1640). In these 11 studies, AUROC curves ranged from 0.69 to 0.90. Heterogeneity in the studies was statistically significant.

In the Crossan et al (2015) systematic review, 6 studies were included in the pooled estimate of the diagnostic accuracy of FibroTest for significant fibrosis (stage ≥F2) in HBV. The cutoffs for positivity ranged from 0.40 to 0.48, and the summary sensitivities and specificities were 66% (95% CI, 57% to 75%) and 80% (95% CI, 72% to 86%), respectively. The accuracy for diagnosing cirrhosis in HBV was...
based on 4 studies with cutoffs for positivity ranging from 0.58 to 0.74; sensitivities and specificities were 74% (95% CI, 25% to 96%) and 90% (95% CI, 83% to 94%), respectively.

**Clinically Useful**
A test is clinically useful if the use of the results informs management decisions that improve the net health outcome of care. The net health outcome can be improved if patients receive correct therapy, more effective therapy, or avoid unnecessary therapy or testing.

**Direct Evidence**
Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. Because these are intervention studies, the preferred evidence would be from RCTs.

There are no studies evaluating the effect of this test on outcomes for patients with HBV. Of note, some researchers have suggested that different markers (e.g., HBV FibroSURE) may be needed for this assessment in patients with hepatitis B.

**Chain of Evidence**
Indirect evidence on clinical utility rests on clinical validity. If the evidence is insufficient to demonstrate test performance, no inferences can be made about clinical utility.

**Section Summary: FibroSURE Serum Panel**
For individuals who have chronic liver disease who receive FibroSURE serum panels, the evidence includes systematic reviews of more than 30 observational studies (>5000 patients). FibroSURE has been studied in populations with viral hepatitis, NAFLD, and ALD. There are established cutoffs, although they were not consistently used in validation studies. Given these limitations and the imperfect reference standard, it is difficult to interpret performance characteristics. However, for the purposes of deciding whether a patient has severe fibrosis or cirrhosis, FibroSURE results provide data sufficiently useful to determine therapy. Specifically, FibroSURE has been used as an alternative to biopsy to establish eligibility regarding the presence of fibrosis or cirrhosis in several RCTs that showed the efficacy of HCV treatments, which in turn demonstrated that the test can identify patients who would benefit from therapy.

**Multianalyte Serum Assays Other Than FibroSURE**

**Clinical Context and Test Purpose**
The purpose of noninvasive testing in individuals with chronic liver disease is to detect liver fibrosis so that patients can avoid the potential adverse events of an invasive liver biopsy and receive appropriate treatment. The degree of liver fibrosis is an important factor in determining the appropriate approach for managing patients with liver disease (e.g., hepatitis, ALD, NAFLD).

The question addressed in this portion of the evidence review is: Does the use of the multianalyte serum assays (other than FibroSURE) for detecting liver fibrosis improve the net health outcome in patients with chronic liver disease?

The following PICO was used to select literature to inform this review.

**Populations**
The relevant population of interest is individuals with chronic liver disease.

**Interventions**
The tests being considered are multianalyte serum assays (other than FibroSURE).
Comparators
The following tests and practices are currently being used to diagnose chronic liver disease: liver biopsy, noninvasive radiologic methods, and other multianalyte serum assays.

Outcomes
The general outcomes of interest are test validity, morbid events, and treatment-related morbidity. Follow-up over months to years is of interest to the relevant outcomes.

Study Selection Criteria
For the evaluation of the clinical validity of the tests within this review, studies that meet the following eligibility criteria were considered:

- Reported on the accuracy of the marketed version of the technology (including any algorithms used to calculate scores).
- Included a suitable reference standard (describe the reference standard).
- Patient/sample clinical characteristics were described.
- Patient/sample selection criteria were described.

FIBROSpect II
Clinically Valid
A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

Review of Evidence
Patel et al (2004) investigated the use of serum markers in an initial training set of 294 patients with HCV and further validated the resulting algorithm in a validation set of 402 patients. The algorithm was designed to distinguish between no or mild fibrosis (F0 to F1) and moderate-to-severe fibrosis (F2 to F4). With the prevalence of F2 to F4 disease of 52% and a cutoff value of 0.36, the PPVs and NPVs were 74.3% and 75.8%, respectively.

The published studies for this combination of markers continue to focus on test characteristics such as sensitivity, specificity, and accuracy. In Crossan et al (2015), the summary diagnostic accuracy for detecting significant fibrosis (stage ≥F2) in 5 studies of HCV with FIBROSpect II, with cutoffs ranging from 42 to 72, was 78% (95% CI, 49% to 93%) and the summary specificity was 71% (95% CI, 59% to 80%).

Clinically Useful
A test is clinically useful if the use of the results informs management decisions that improve the net health outcome of care. The net health outcome can be improved if patients receive correct therapy, more effective therapy, or avoid unnecessary therapy or testing.

Direct Evidence
Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. Because these are intervention studies, the preferred evidence would be from RCTs.

The issues of effect on patient outcomes are similar to those discussed for the FibroSURE (FibroTest in Europe). No studies were identified in the published literature in which the results of the FIBROSpect test were actively used in the management of the patient.

Chain of Evidence
Indirect evidence on clinical utility rests on clinical validity. If the evidence is insufficient to demonstrate test performance, no inferences can be made about clinical utility.
Because the clinical validity of FIBROSpect has not been established, a chain of evidence supporting the clinical utility of this test for this population cannot be constructed.

**Other Multianalyte Scoring Systems**

**Clinically Valid**

A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

**Review of Evidence**

Other scoring systems have been developed, including FIB-4, NAFLD fibrosis score (NFS), APRI, AST/ALT ratio, combined body mass index, AST/ALT ratio and diabetes status (BARD), and Enhanced Liver Fibrosis (ELF). The ELF test combines measurements of biomarkers into a proprietary algorithm to produce a score. The other scoring systems use a simple nonproprietary formula that can be calculated at the bedside to produce a score for the prediction of fibrosis. Tables 1 and 2 summarize the characteristics and results of systematic reviews that have assessed the diagnostic accuracy of various noninvasive scoring systems. There are no established cutoffs for ruling in or ruling out advanced fibrosis for most tests. In the systematic reviews, 2 cutoffs were analyzed for each test (as selected by the authors); a lower threshold to rule out advanced fibrosis and a higher threshold to rule in advanced fibrosis. Patients that fall between the 2 thresholds are classified as "indeterminate" risk for whom a liver biopsy may be considered. Castellana et al (2021) conducted an meta-analytic head-to-head comparison between FIB-4 and NFS and found no significant differences regarding relative diagnostic OR, positive likelihood ratio, and negative likelihood ratio. FIB-4 was associated with fewer indeterminate findings compared to NFS. Mozes et al (2021) found that FibroScan, a transient elastography test, outperformed all of the serum-based tests. Sharma et al (2021) qualitatively evaluated the diagnostic performance of ELF in patients with chronic liver disease.

ALD: alcoholic liver disease; ALT: alanine aminotransferase; APRI: aminotransferase-to-platelet ratio index; AST: aspartate aminotransferase; AUROC: area under the receiver operating characteristic; CI: confidence interval; ELF: enhanced liver fibrosis; FIB-4: fibrosis-4 index; HBV: hepatitis B virus; HCV: hepatitis C virus; NAFLD: nonalcoholic fatty liver disease; NE: not evaluated; NFS: NAFLD fibrosis score; NR: not reported.

**Table 3. Diagnostic Accuracy for Aminotransferase to Platelet Ratio Index**

The APRI requires only the serum level of AST and the number of platelets as part of its calculation. Using an optimized cutoff value derived from a training set and validation set of patients with HCV, authors have reported that the NPV for fibrosis was 86% and that the PPV was 88%. In Crossan et al (2015), APRI was frequently evaluated and has been tested in HCV, HBV, NAFLD, and ALD. The summary diagnostic accuracies are in Table 3.

Adapted from Crossan et al (2015).5
ALD: alcoholic liver disease; APRI: aspartate aminotransferase-platelet ratio index; CI: confidence interval; HBV: hepatitis B virus; HCV: hepatitis C virus; NA: not available; NAFLD: nonalcoholic fatty liver disease.

Giannini et al (2006) reported that the use of the AST/ALT ratio and platelet counts in a diagnostic algorithm would have avoided liver biopsy in 69% of patients with chronic hepatitis C and would have correctly identified the absence or presence of significant fibrosis in 80.5% of these cases.6 In Crossan et al (2015), the cutoffs for the positivity of AST/ALT ratio for diagnosis of significant fibrosis (stage ≥F2) varied from 0.6 to 1 in 7 studies.5 Summary sensitivity and specificity were 44% (95% CI, 27% to 63%) and 71% (95% CI, 62% to 78%), respectively. Thirteen studies used a cutoff of 1 to estimate the diagnostic accuracy of cirrhosis with the AST/ALT ratio, and summary sensitivity and specificity were 49% (95% CI, 39% to 59%) and 87% (95% CI, 75% to 94%), respectively.

A number of studies have compared HCV FibroSURE (FibroTest) and other noninvasive tests of fibrosis with biopsy using receiver operating characteristic (ROC) analysis. For example, Bourliere et al (2006) reported on the validation of FibroSURE (FibroTest) and found that, based on ROC analysis, FibroSURE (FibroTest) was superior to APRI for identifying significant fibrosis, with AUROC curves of 0.81 and 0.71, respectively.37 A prospective multicenter study by Zarksi et al (2012) compared 9 of the best-evaluated blood tests in 436 patients with HCV and found similar performance for HCV FibroSURE (FibroTest), FibroMeter, and HepaScore (ROC curve, 0.84, 0.86, 0.84, respectively).38 These 3 tests were significantly superior to the 6 other tests, with 70% to 75% of patients considered well-classified according to a dichotomized score (F0/F1 vs ≥F2). The number of “theoretically avoided liver biopsies” for the diagnosis of significant fibrosis was calculated to be 35.6% for HCV FibroSURE (FibroTest). To improve diagnostic accuracy, algorithms that combine HCV FibroSURE (FibroTest) with other tests (e.g., APRI) are also being evaluated.38,39,40 One of these, the sequential algorithm for fibrosis evaluation, combines the APRI and FibroTest. Crossan et al (2015) reported that the algorithm has been assessed in 4 studies of HCV for diagnosing both significant fibrosis (stage ≥F2) and cirrhosis.5 Summary sensitivity and specificity for significant fibrosis were estimated to be 100% (95% CI, 100% to 100%) and 81% (95% CI, 80% to 83%), respectively. The summary sensitivity and specificity for cirrhosis were 74% (95% CI, 42% to 92%) and 93% (95% CI, 91% to 94%), respectively.

Rosenberg et al (2004) developed a scoring system based on an algorithm combining hyaluronic acid, amino-terminal propeptide of type III collagen, and tissue inhibitors of metalloproteinase 1.41 This test is manufactured by Siemens Healthcare as the ELF Test.42 The algorithm was developed in a test set of 400 patients with a wide variety of chronic liver diseases and then validated in another 521 patients. The algorithm was designed to discriminate between no or mild fibrosis and moderate-to-severe fibrosis. The NPV for fibrosis was 92%.

Younossi et al (2021) evaluated the diagnostic value of ELF to assess liver fibrosis in patients with NAFLD.43 This was a retrospective, cross-sectional study including 829 patients; 462 had transient elastography data and 463 had liver biopsy data. A significant increase in ELF scores was correlated in patients with advanced fibrosis by biopsy or transient elastography. The AUROC for ELF for identifying fibrosis was 0.81 (95% CI, 0.77 to 0.85) with biopsy as the reference standard and 0.79 (95% CI, 0.75 to 0.82) with transient elastography as the reference standard. Predictive combinations of ELF and FIB-4 scores were additionally evaluated. For ELF score ≥7.2 with a FIB-4 score ≥0.74, the sensitivity and NPV were 92.5% (95% CI, 87.4% to 97.5%) and 95.1% (95% CI, 91.8% to 98.4%), respectively, for ruling out fibrosis. For ELF score ≥9.8 with a FIB-4 score ≥2.9, the specificity and PPV were 99.7% (95% CI, 99.1% to 100%) and 95.0% (95% CI, 85.5% to 100%), respectively, for ruling in fibrosis.
The FIB-4 index was developed in a cohort of patients with HCV and is similar to APRI in that it uses a simple nonproprietary formula to produce a score for the prediction of fibrosis, incorporating patient age, AST level, ALT level, and platelet count. In the original cohort studied by Sterling et al (2006)\(^4\), a low cutoff score of <1.45 had an NPV of 90% for advanced fibrosis whereas a high cutoff score >3.25 had a 97% specificity and PPV of 65% for advanced fibrosis. Overall, 70% of patients were stratified <1.45 or >3.25 and represented potential cases that could have avoided liver biopsy with a corresponding diagnostic accuracy of 86%. In a comparative study by Vallet-Pichard et al (2007) in patients with HCV utilizing the same cutoff values, an NPV of 94.7% with a sensitivity of 74.3% and a specificity of 80.1% and a PPV of 82.1% with a specificity of 98.2% and sensitivity of 37.6% were reported.\(^4\) When the diagnostic performance of FIB-4 was compared against FibroTest (FibroSure in the U.S.), the exclusion of severe fibrosis and the detection of severe fibrosis were found to agree between the tests in 92.1% and 76.0% of cases, respectively.

Yan et al (2020) evaluated the diagnostic value of total bile acid-to-cholesterol ratio (TBA/TC) as a serum marker for cirrhosis and fibrosis in chronic HBV-infected patients without cholestasis.\(^4\) This was a cross-sectional study including 667 patients. In a multivariate analysis, TBA/TC was independently correlated with cirrhosis in the study population (OR, 1.102; 95% CI, 1.085 to 1.166). ROC curve analyses yielded similar areas under the curve (AUCs) for TBA/TC, APRI, and FIB-4 at 0.87, 0.84, and 0.80, respectively. For diagnosing cirrhosis, the specificity and PPV of TBA/TC (83.33%, 91.10%) were higher than those of APRI (73.61%, 87.20%). The AUC of TBA/TC that distinguished significant liver cirrhosis was 2.70. In another multivariate analysis, TBA/TC was also independently correlated with significant fibrosis (OR, 1.040; 95% CI, 1.001 to 1.078). The AUC of TBA/TC that distinguished significant liver fibrosis was 0.70. Among 32 patients who also had a liver biopsy performed, TBA/TC was significantly higher in both fibrosis and cirrhosis as well as significantly correlated with fibrosis stage (p<.001 for all).

Clinical Useful
A test is clinically useful if the use of the results informs management decisions that improve the net health outcome of care. The net health outcome can be improved if patients receive correct therapy, more effective therapy, or avoid unnecessary therapy or testing.

Direct Evidence
Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. Because these are intervention studies, the preferred evidence would be from RCTs. The primary benefit of the multivariate serum assays is the ability to avoid liver biopsy.

A systematic review and meta-analysis conducted by Cianci et al (2022) evaluated the use of noninvasive biomarkers for prediction of all-cause and cardiovascular mortality in patients with NAFLD.\(^4\) Of 24 studies included in the review, noninvasive scoring systems were assessed in 16 studies, 4 of which had adequate data for meta-analysis based on review criteria that required 2 or more studies reporting the same outcome measure using equivalent cut-off values and statistical methods in a similar study population. All of the studies included in the meta-analysis studies were retrospective (N=9,725; n range=320 to 4,680), and NAFLD diagnosis was based on liver biopsy or clinical diagnosis. Mean duration of follow-up ranged from 9 to 20 years in 3 of the studies and was not reported in the fourth study, but the total study duration was 17 years. A total of 1,697 deaths were reported in the 4 studies. Results of the meta-analyses appear in Table 4. Although high scores were associated with an increased risk of mortality relative to low scores across all scoring systems, the evidence is limited by the small number of included studies and high heterogeneity and imprecision for some estimates.

Adapted from Cianci et al 202247.

ALT: alanine aminotransferase; APRI: aminotransferase-to-platelet ratio index; AST: aspartate aminotransferase; BARD: body mass index, AST/ALT ratio and diabetes status; CI: confidence interval; FIB-4: fibrosis-4 index; HR: hazard ratio; NAFLD: nonalcoholic fatty liver disease; NFS: NAFLD fibrosis score.

Sanyal et al (2019) reported on findings of 2, phase 2b, placebo-controlled trials of simtuzumab in NASH in patients with bridging fibrosis (F3; n=217) or compensated cirrhosis (F4; n=258) that assessed patients with liver biopsy and serum biomarker tests, including ELF, APRI, FibroSure/FibroTest, and the FIB-4 index.48, Laboratory screening was conducted at baseline and at every 3 months during the course of the trials. The trials were terminated after 96 weeks due to simtuzumab inefficacy, at which point data from treatment groups were combined for analysis. In patients with bridging fibrosis, increased risk of progression to cirrhosis was observed with higher baseline levels of all serum fibrosis tests (p<.001). Change in the ELF score over time was also associated with progression to cirrhosis (p<.001). For a cutoff score of 9.76, progression to cirrhosis had a reported hazard ratio (HR) of 4.12 (95% CI, 2.14 to 7.93; p<.001). For patients with compensated cirrhosis, higher levels of baseline biomarker tests were also associated with liver-related clinical events in 19% of patients, such as ascites, hepatic encephalopathy, newly diagnosed varices, esophageal variceal bleed, increase in Child-Pugh and/or model for end-stage liver disease (MELD) score, or death (p<.001 to.006). While the manufacturer of the test differentiates moderate from severe fibrosis with a cutoff ELF score of 9.8, current National Institute for Health and Care Excellence guidelines for NAFLD recommend reserving a diagnosis of advanced fibrosis to NAFLD patients with an ELF score of 10.51 or greater, limiting the clinical significance of these findings.49, Furthermore, serum fibrosis test results were not directly used in patient management in the simtuzumab trials.

Chain of Evidence
Indirect evidence on clinical utility rests on clinical validity. If the evidence is insufficient to demonstrate test performance, no inferences can be made about clinical utility.

Section Summary: Multianalyte Serum Assays Other Than FibroSURE
For individuals who have chronic liver disease who receive multianalyte serum assays for liver function assessment other than FibroSURE, the evidence includes a number of observational studies and systematic reviews of those studies. Studies have frequently included varying cutoffs, some of which were standardized and others not validated. Cutoff thresholds have often been modified over time, may be specific to certain patient populations, and in some cases, guideline recommendations...
differ from cutoffs designated by manufacturers and those utilized in studies. A comparison of transient elastography to various serum-based tests found that the former were superior in detecting fibrosis, and a meta-analysis of 4 studies found higher multianalyte scores associated with an increased risk of mortality relative to lower scores, but the evidence is limited by the small number of included studies and high heterogeneity and imprecision for some estimates. Given these limitations and the imperfect reference standard, it is difficult to interpret performance characteristics. There is no direct evidence that other multianalyte serum assays improve health outcomes; further, it is not possible to construct a chain of evidence for clinical utility due to the lack of sufficient evidence on clinical validity. FIBROSpect II has been studied in populations with HCV. Cutoffs for positivity varied across studies and were not well validated. The methodologic quality of the validation studies was generally poor. There is no direct evidence that FIBROSpect II improves health outcomes.

Noninvasive Imaging: Transient Elastography
Clinical Context and Test Purpose
The purpose of noninvasive testing in individuals with chronic liver disease is to detect liver fibrosis so that patients can avoid the potential adverse events of an invasive liver biopsy and receive appropriate treatment. The degree of liver fibrosis is an important factor in determining the appropriate approach for managing patients with liver disease (e.g., hepatitis, ALD, NAFLD).

The question addressed in this portion of the evidence review is: Does the use of transient elastography for detecting liver fibrosis improve the net health outcome in patients with chronic liver disease?

The following PICO was used to select literature to inform this review.

**Populations**
The relevant population of interest is individuals with chronic liver disease.

**Interventions**
The test being considered is transient elastography.

**Comparators**
The following tests and practices are currently being used to diagnose chronic liver disease: liver biopsy, other noninvasive radiologic methods, and multianalyte serum assays.

**Outcomes**
The general outcomes of interest are test validity, morbid events, and treatment-related morbidity. Follow-up over months to years is of interest to the relevant outcomes.

**Study Selection Criteria**
For the evaluation of the clinical validity of the tests within this review, studies that meet the following eligibility criteria were considered:
- Reported on the accuracy of the marketed version of the technology (including any algorithms used to calculate scores).
- Included a suitable reference standard (describe the reference standard).
- Patient/sample clinical characteristics were described.
- Patient/sample selection criteria were described.

**Clinically Valid**
A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).
Review of Evidence
There is extensive literature on the use of transient elastography (e.g., FibroScan) to gauge liver fibrosis and cirrhosis. Summaries of systematic reviews are shown in Tables 5 and 6. Brener (2015) performed a health technology assessment summarizing many of the systematic reviews below.50, The assessment focused on reviews of the diagnostic accuracy and effect on patient outcomes of transient elastography for liver fibrosis in patients with HCV, HBV, NAFLD, ALD, or cholestatic diseases. Fourteen systematic reviews of transient elastography with biopsy reference standard shown below were included in the Brener assessment, summarizing more than 150 primary studies.51,52,53,54,55,56,57,58,59,60,61,62,63,64, There was variation in the underlying cause of liver disease and the cutoff values of transient elastography stiffness used to define Metavir stages in the systematic reviews. There did not appear to be a substantial difference in diagnostic accuracy for 1 disease over any other. The reviews demonstrated that transient elastography has good diagnostic accuracy compared with biopsy for the assessment of liver fibrosis and steatosis.

Crossan et al (2015) found that FibroScan was the noninvasive liver test most assessed in validation studies across liver diseases (37 studies in HCV, 13 in HBV, 8 in NAFLD, 6 in ALD).5 Cutoffs for positivity for fibrosis staging varied between diseases and were frequently not prespecified or validated: HCV, 5.2 to 10.1 kilopascal (kPa) in the 37 studies for Metavir stages ≥F2; HBV, 6.3 to 8.9 kPa in 13 studies for stages ≥F2; NAFLD, 7.5 to 10.4 kPa in 8 studies for stages ≥F3; ALD, 11.0 to 12.5 kPa in 4 studies for stages ≥F3. Summary sensitivities and specificities by disease are shown in Table 6. The overall sensitivity and specificity for cirrhosis including all diseases (65 studies; cutoffs range, 9.2 to 26.5 kPa) were 89% (95% CI, 86% to 91%) and 89% (95% CI, 87% to 91%), respectively. The rate of uninterpretable results, when reported, with FibroScan (due to <10 valid measurements; success rate, <60%; interquartile range, >30%) was 8.5% in HCV and 9.6% in NAFLD.

Clinically Useful
A test is clinically useful if the use of the results informs management decisions that improve the net health outcome of care. The net health outcome can be improved if patients receive correct therapy, more effective therapy, or avoid unnecessary therapy or testing.

Direct Evidence
Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. Because these are intervention studies, the preferred evidence would be from RCTs.

There are currently no published studies that directly demonstrate the effect of transient elastography (e.g., FibroScan) on patient outcomes.

FibroScan is used extensively in practice to make management decisions. In addition, FibroScan was used as an alternative to biopsy to diagnose fibrosis or cirrhosis to establish trial eligibility in several trials (ION-1,-3; VALENCE; ASTRAL-2,-3,-4) that confirmed the efficacy of HCV treatments. For example, in the VALENCE trial, cirrhosis could be defined by liver biopsy or a confirmatory FibroTest or FibroScan result at 12.5 kPa or greater. In VALENCE, FibroScan was used to determine cirrhosis in 74% of the participants. In a retrospective, multicenter analysis of 7256 chronic HCV patients by Abdel Alem et al (2019), both transient elastography and FIB-4 were found to be predictors of treatment failure to sofosbuvir-based treatment regimens with an NPV of 95%.

Chain of Evidence
Indirect evidence on clinical utility rests on clinical validity. If the evidence is insufficient to demonstrate test performance, no inferences can be made about clinical utility.

Section Summary: Transient Elastography (FibroScan)
For individuals who have chronic liver disease who receive transient elastography (e.g., FibroScan), the evidence includes many systematic reviews of more than 50 observational studies (>10,000 patients). Transient elastography has been studied in populations with viral hepatitis, NAFLD, and ALD. There are varying cutoffs for positivity. Failures of the test are not uncommon, particularly for those with high body mass index, but these failures often went undetected in analyses of the validation studies. Given these limitations and the imperfect reference standard, it can be difficult to interpret performance characteristics. However, for the purposes of deciding whether a patient has severe fibrosis or cirrhosis, the FibroScan results provide data sufficiently useful to determine therapy. In fact, FibroScan has been used as an alternative to biopsy to establish eligibility regarding the presence of fibrosis or cirrhosis in the participants of several RCTs. These trials showed the efficacy of HCV treatments, which in turn demonstrated that the test can identify patients who would benefit from therapy.

Noninvasive Imaging: Multiparametric Magnetic Resonance Imaging
Clinical Context and Test Purpose
The purpose of noninvasive testing in individuals with chronic liver disease is to detect liver fibrosis so that patients can avoid the potential adverse events of an invasive liver biopsy and receive appropriate treatment. The degree of liver fibrosis is an important factor in determining the appropriate approach for managing patients with liver disease (e.g., hepatitis, ALD, NAFLD).

The question addressed in this portion of the evidence review is: Does the use of multiparametric magnetic resonance imaging (MRI) for detecting liver fibrosis improve the net health outcome in patients with chronic liver disease?

The following PICO was used to select literature to inform this review.
Populations
The relevant population of interest is individuals with chronic liver disease.

Interventions
The test being considered is multiparametric MRI (e.g., LiverMultiScan).

Comparators
The following tests and practices are currently being used to diagnose chronic liver disease: liver biopsy, other noninvasive radiologic methods, and multianalyte serum assays.

Outcomes
The general outcomes of interest are test validity, morbid events, and treatment-related morbidity. Follow-up over months to years is of interest to the relevant outcomes.

Study Selection Criteria
For the evaluation of the clinical validity of the tests within this review, studies that meet the following eligibility criteria were considered:

- Reported on the accuracy of the marketed version of the technology (including any algorithms used to calculate scores).
- Included a suitable reference standard (describe the reference standard).
- Patient/sample clinical characteristics were described.
- Patient/sample selection criteria were described.

Clinically Valid
A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

Review of Evidence
Tables 7 and 8 summarize studies that have evaluated the diagnostic accuracy of multiparametric MRI, which incorporates assessment of proton density fat-fraction, $T_2^*$, and $T_1$ mapping to characterize liver fat, iron, fibrosis, and inflammation. Generally, technical failures were less common with MRI than transient elastography.73,74,75.

Jayaswal et al (2020) compared the prognostic value of MRI cT1 measurements, transient elastography, and multianalyte serum assays in a cohort of 197 patients with compensated chronic liver disease. Patients who were referred for a clinically indicated liver biopsy, or with a known diagnosis of liver cirrhosis, were eligible. At baseline, patients underwent multiparametric MRI scans, transient elastography, and blood tests. Additionally, all patients received a liver biopsy and had their fibrosis rated on the Ishak scale; results of the biopsies informed clinical care. The most common underlying disease states were NAFLD (n=85, 43%), viral hepatitis (n=50, 25%), and ALD (n=22, 11%). The primary endpoint was a composite of ascites, variceal bleeding, hepatic encephalopathy, hepatocellular carcinoma, liver transplantation and mortality. Binary cutoff values were predefined. Patients were followed for a median of 43 months. Over this period, 14 new clinical events were recorded, including 11 deaths. The prognostic value of the noninvasive testing is summarized in Table 9. Technical failures were also reported (e.g., poor quality scan); reliable measurements were obtained in 182 of 197 (92%) patients for multiparametric MRI and in 121 of 160 (76%) patients for transient elastography (transient elastography was additionally not attempted in 37 patients). The study was limited by having variable follow-up periods and the effect of patients being censored at different time points was not taken into account, so sensitivities, specificities, PPVs and NPVs should be interpreted cautiously. The CI for the survival analysis were wide likely due to the relatively small number of new clinical events observed.

Pavlides et al (2016) evaluated whether data obtained from multiparametric MRI was predictive of all-cause mortality and liver-related clinical events. Patients who were referred for a clinically indicated liver biopsy, or with a diagnosis of liver cirrhosis on MRI scan, were eligible. Liver-related
clinical events were defined as liver-related death, hepatocellular carcinoma, and new hepatic decompensation (i.e., clinically evident ascites, variceal bleeding, and hepatic encephalopathy). Patients received multiparametric MRI and liver cT1 values were mapped into a Liver Inflammation and Fibrosis (LIF) score. One hundred twenty three patients were recruited to the study; 6 were excluded due to claustrophobia or incomplete MRI data. Of the 117 patients who had complete MRI data, follow-up data were available for 112; the study reported outcomes on these 112 patients. The most common underlying disease states were NAFLD (35%), viral hepatitis (30%), and ALD (10%). Over a median follow-up time of 27 months, 10 patients had a liver-related clinical event and 6 patients died. No patients who had a LIF <2 (no or mild liver disease) developed a clinical event. Ten of 56 (18%) patients with a LIF ≥2 (moderate or severe liver disease) experienced a clinical event. A study limitation is the use of LIF scores, which are no longer used in clinical practice. The authors further described the study as a small proof of principle study.

Clinically Useful
A test is clinically useful if the use of the results informs management decisions that improve the net health outcome of care. The net health outcome can be improved if patients receive correct therapy, more effective therapy, or avoid unnecessary therapy or testing.

Direct Evidence
Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. Because these are intervention studies, the preferred evidence would be from RCTs. The primary benefit of multiparametric MRI for chronic liver disease is the ability to avoid liver biopsy in patients without significant fibrosis. There are currently no such published studies to demonstrate the effect on patient outcomes.

Multiparametric MRI has been used as an alternative to biopsy for measuring fibrosis or cirrhosis in clinical trials. Phase 2 clinical trials have used multiparametric MRI to measure therapeutic efficacy of an investigational treatments for NASH78, and NAFLD.79.

The utility of multiparametric MRI to provide clinically useful information on the presence and extent of liver fibrosis and inflammation has been evaluated in smaller prospective studies. Specifically, it has been evaluated in the setting of biochemical remission in liver diseases where noninvasive testing for continued disease activity could further aid in direct management of patients as a prognostic marker of future liver-related complications. Quantitative multiparametric MRI has been used to measure disease burden after treatment in patients with chronic HCV80, and autoimmune hepatitis.81,82,83,84.

Currently, there is not evidence that demonstrates that the use of the test for response to therapy impacts decision making and that these changes in management decisions lead to improved outcomes.

Chain of Evidence
Indirect evidence on clinical utility rests on clinical validity. If the evidence is insufficient to demonstrate test performance, no inferences can be made about clinical utility.

Section Summary: Multiparametric Magnetic Resonance Imaging
For individuals who have chronic liver disease who receive multiparametric MRI, the evidence includes several prospective and retrospective observational studies. Multiparametric MRI (e.g., LiverMultiScan) has been studied in mixed populations, including NAFLD, viral hepatitis, and ALD. Quantitative MRI provides various measures assessing both liver fat content and fibrosis and inflammation. Various cutoffs have been utilized for positivity. Generally, multiparametric MRI performed similarly to transient elastography, and fewer technical failures of multiparametric MRI were reported. Given these limitations and the imperfect reference standard, it can be difficult to interpret performance characteristics. The prognostic ability of quantitative MRI to predict liver-
related clinical events has been evaluated in 2 studies; both reported positive correlations with wide CIs. Larger cohorts with a longer follow-up time would be useful to further derive the prognostic ability. Additionally, multiparametric MRI has been used to measure the presence of fibrosis or cirrhosis in the patients who have achieved biochemical remission after treatment in small prospective studies.

Other Noninvasive Imaging

Clinical Context and Test Purpose

The purpose of noninvasive testing in individuals with chronic liver disease is to detect liver fibrosis so that patients can avoid the potential adverse events of an invasive liver biopsy and receive appropriate treatment. The degree of liver fibrosis is an important factor in determining the appropriate approach for managing patients with liver disease (e.g., hepatitis, ALD, NAFLD).

The question addressed in this portion of the evidence review is: Does the use of other noninvasive imaging for detecting liver fibrosis improve the net health outcome in patients with chronic liver disease?

The following PICO was used to select literature to inform this review.

Populations

The relevant population of interest is individuals with chronic liver disease.

Interventions

The tests being considered are other noninvasive imaging, including magnetic resonance elastography (MRE), ARFI (e.g., Acuson S2000), and real-time tissue elastography (RTE; e.g., HI VISION Preirus).

Comparators

The following tests and practices are currently being used to diagnose chronic liver disease: liver biopsy, other noninvasive radiologic methods, and multianalyte serum assays.

Outcomes

The general outcomes of interest are test validity, morbid events, and treatment-related morbidity. Follow-up over months to years is of interest to the relevant outcomes.

Study Selection Criteria

For the evaluation of the clinical validity of the tests within this review, studies that meet the following eligibility criteria were considered:

- Reported on the accuracy of the marketed version of the technology (including any algorithms used to calculate scores).
- Included a suitable reference standard (describe the reference standard).
- Patient/sample clinical characteristics were described.
- Patient/sample selection criteria were described.

Acoustic Radiation Force Impulse Imaging

Clinically Valid

A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

Review of Evidence

AUROC: area under the receiver operating characteristic curve; CI: confidence interval; HBV: hepatitis B virus; HCV: hepatitis C virus; NAFLD: nonalcoholic fatty liver disease; NR: not reported.

Clinically Useful
A test is clinically useful if the use of the results informs management decisions that improve the net health outcome of care. The net health outcome can be improved if patients receive correct therapy, more effective therapy, or avoid unnecessary therapy or testing.

Direct Evidence
Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. Because these are intervention studies, the preferred evidence would be from RCTs.
There are currently no published studies that directly demonstrate the effect of ARFI imaging on patient outcomes.

**Chain of Evidence**
Indirect evidence on clinical utility rests on clinical validity. If the evidence is insufficient to demonstrate test performance, no inferences can be made about clinical utility.

Because the clinical validity of ARFI imaging has not been established, a chain of evidence supporting the clinical utility of this test for this population cannot be constructed.

**Magnetic Resonance Elastography**
**Clinically Valid**
A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

**Review of Evidence**
Tables 12 and 13 summarize the characteristics and results of systematic reviews that have assessed the diagnostic accuracy of MRE. MRE has been studied primarily in hepatitis and NAFLD.

**Clinically Useful**
A test is clinically useful if the use of the results informs management decisions that improve the net health outcome of care. The net health outcome can be improved if patients receive correct therapy, more effective therapy, or avoid unnecessary therapy or testing.
Direct Evidence
Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. Because these are intervention studies, the preferred evidence would be from RCTs.

There are currently no published studies that directly demonstrate the effect of MRE on patient outcomes.

Chain of Evidence
Indirect evidence on clinical utility rests on clinical validity. If the evidence is insufficient to demonstrate test performance, no inferences can be made about clinical utility.

Because the clinical validity of MRE has not been established, a chain of evidence supporting the clinical utility of this test for this population cannot be constructed.

Real-Time Tissue Elastography (HI VISION 15 Preirus)
Clinically Valid
A test must detect the presence or absence of a condition, the risk of developing a condition in the future, or treatment response (beneficial or adverse).

Review of Evidence
Kobayashi et al (2015) published the results of a meta-analysis assessing RTE for staging liver fibrosis. The authors selected 15 studies (N=1626) published through December 2013, including patients with multiple liver diseases and healthy adults. A bivariate random-effects model was used to estimate summary sensitivity and specificity. The summary AUROC, sensitivity, and specificity were 0.69, 79% (95% CI, 75% to 83%), and 76% (95% CI, 68% to 82%) for detection of significant fibrosis (stage ≥F2), and 0.72, 74% (95% CI, 63% to 82%), and 84% (95% CI, 79% to 88%) for detection of cirrhosis, respectively. Reviewers found evidence of heterogeneity due to differences in study populations, scoring methods, and cutoffs for positivity. They also found evidence of publication bias based on funnel plot asymmetry.

Hong et al (2014) reported on the results of a meta-analysis evaluating RTE for staging fibrosis in multiple diseases. Thirteen studies (N=1,347) published between April 2000 and April 2014 that used a liver biopsy or transient elastography as the reference standard were included. Different quantitative methods were used to measure liver stiffness in the included studies: Liver Fibrosis Index (LFI), Elasticity Index, elastic ratio 1 (ER1), and elastic ratio 2. For predicting significant fibrosis (stage ≥F2), the pooled sensitivities for LFI and ER1 were 78% (95% CI, 70% to 84%) and 86% (95% CI, 80% to 90%), respectively. The specificities were 63% (95% CI, 46% to 78%) and 89% (95% CI, 83% to 94%) and the AUROCs were 0.79 (95% CI, 0.75 to 0.82) and 0.94 (95% CI, 0.92 to 0.96), respectively. For predicting cirrhosis (stage F4), the pooled sensitivities of LFI, ER1, and elastic ratio 2 were 79% (95% CI, 61% to 91%), 96% (95% CI, 87% to 99%), and 79% (95% CI, 61% to 91%), respectively. The specificities were 88% (95% CI, 81% to 93%) for LFI, 89% (95% CI, 83% to 93%) for ER1, and 88% (95% CI, 81% to 93%) for elastic ratio 2, and the AUROCs were 0.85 (95% CI, 0.81 to 0.87), 0.93 (95% CI, 0.94 to 0.98), and 0.92 (95% CI, not reported), respectively. Pooled estimates for Elasticity Index were not performed due to insufficient data.

Clinically Useful
A test is clinically useful if the use of the results informs management decisions that improve the net health outcome of care. The net health outcome can be improved if patients receive correct therapy, more effective therapy, or avoid unnecessary therapy or testing.
Direct Evidence
Direct evidence of clinical utility is provided by studies that have compared health outcomes for patients managed with and without the test. Because these are intervention studies, the preferred evidence would be from RCTs.

There are currently no published studies that directly demonstrate the effect of RTE on patient outcomes.

Chain of Evidence
Indirect evidence on clinical utility rests on clinical validity. If the evidence is insufficient to demonstrate test performance, no inferences can be made about clinical utility.

Because the clinical validity of RTE has not been established, a chain of evidence supporting the clinical utility of this test for this population cannot be constructed.

Section Summary: Noninvasive Radiological Methods Other Than Transient Elastography
The use of ARFI imaging has been evaluated in viral hepatitis and NAFLD. Moreover, many have noted that ARFI imaging has potential advantages over FibroScan. ARFI can be implemented on a standard ultrasound machine, may be more applicable for assessing complications such as ascites, and may be more applicable in obese patients. ARFI imaging appears to have similar diagnostic accuracy to FibroScan, but there are fewer data available on performance characteristics. Validation studies have used varying cutoffs for positivity. MRE has a high success rate and is highly reproducible. The diagnostic accuracy also appears to be high. In particular, MRE has high diagnostic accuracy for the detection of fibrosis in NAFLD, independent of body mass index and degree of inflammation. However, further validation is needed to determine standard cutoffs and confirm performance characteristics because CI for estimates are wide. MRE is also not widely available. RTE has been evaluated in multiple diseases with varying scoring methods and cutoffs. Although data are limited, the accuracy of RTE appears to be similar to FibroScan for the evaluation of significant liver fibrosis, but less accurate for the evaluation of cirrhosis. However, there was evidence of publication bias in the systematic review and the diagnostic accuracy may be overestimated.

For individuals who have chronic liver disease who receive noninvasive radiologic methods other than transient elastography for liver fibrosis measurement, the evidence includes systematic reviews of observational studies. Other radiologic methods (e.g., MRE, RTE, ARFI) may have similar performance for detecting significant fibrosis or cirrhosis. Studies have frequently included varying cutoffs not prespecified or validated. Given these limitations and the imperfect reference standard, it is difficult to interpret performance characteristics. There is no direct evidence that other noninvasive radiologic methods improve health outcomes; further, it is not possible to construct a chain of evidence for clinical utility due to the lack of sufficient evidence on clinical validity.

Summary of Evidence
Multianalyte Serum Assays
For individuals who have chronic liver disease who receive FibroSURE serum panels, the evidence includes systematic reviews of more than 30 observational studies (>5000 patients). Relevant outcomes are test validity, morbid events, and treatment-related morbidity. FibroSURE has been studied in populations with viral hepatitis, NASH, and ALD. There are established cutoffs, although they were not consistently used in validation studies. Given these limitations and the imperfect reference standard, it is difficult to interpret performance characteristics. However, for the purposes of deciding whether a patient has severe fibrosis or cirrhosis, FibroSURE results provide data sufficiently useful to determine therapy. Specifically, FibroSURE has been used as an alternative to biopsy to establish eligibility regarding the presence of fibrosis or cirrhosis in several RCTs that showed the efficacy of HCV treatments, which in turn demonstrated that the test can identify patients who would benefit from therapy. The evidence is sufficient to determine that the technology results in an improvement in the net health outcome.
For individuals who have chronic liver disease who receive multianalyte serum assays for liver function assessment other than FibroSURE, the evidence includes a number of observational studies and systematic reviews of those studies. Relevant outcomes are test validity, morbid events, and treatment-related morbidity. Studies have frequently included varying cutoffs, some of which were standardized and others not validated. Cutoff thresholds have often been modified over time, may be specific to certain patient populations, and in some cases, guideline recommendations differ from cutoffs designated by manufacturers and those utilized in studies. A comparison of transient elastography to various serum-based tests found that the former was superior in detecting fibrosis, and a meta-analysis of 4 studies found higher multianalyte scores associated with an increased risk of mortality relative to lower scores, but the evidence is limited by the small number of included studies and high heterogeneity and imprecision for some estimates. Given these limitations and the imperfect reference standard, it is difficult to interpret performance characteristics. There is no direct evidence that other multianalyte serum assays improve health outcomes; further, it is not possible to construct a chain of evidence for clinical utility due to the lack of sufficient evidence on clinical validity. The evidence is insufficient to determine that the technology results in an improvement in the net health outcome.

Noninvasive Imaging

For individuals who have chronic liver disease who receive transient elastography, the evidence includes many systematic reviews of more than 50 observational studies (>10,000 patients). Relevant outcomes are test validity, morbid events, and treatment-related morbidity. Transient elastography (FibroScan) has been studied in populations with viral hepatitis, NASH, and ALD. There are varying cutoffs for positivity. Failures of the test are not uncommon, particularly for those with high body mass index, but these failures often went undetected in analyses of the validation studies. Given these limitations and the imperfect reference standard, it can be difficult to interpret performance characteristics. However, for the purposes of deciding whether a patient has severe fibrosis or cirrhosis, the FibroScan results provide data sufficiently useful to determine therapy. In fact, FibroScan has been used as an alternative to biopsy to establish eligibility regarding the presence of fibrosis or cirrhosis in the participants of several RCTs. These trials showed the efficacy of HCV treatments, which in turn demonstrated that the test can identify patients who would benefit from therapy. The evidence is sufficient to determine that the technology results in an improvement in the net health outcome.

For individuals who have chronic liver disease who receive multiparametric MRI, the evidence includes several prospective and retrospective observational studies. Multiparametric MRI (e.g., LiverMultiScan) has been studied in mixed populations, including NAFLD, viral hepatitis, and ALD. Quantitative MRI provides various measures to assess liver fat content, fibrosis and inflammation. Various cutoffs have been utilized for positivity. Given these limitations and the imperfect reference standard, it can be difficult to interpret performance characteristics. Otherwise, multiparametric MRI performed similarly to transient elastography, and fewer technical failures of multiparametric MRI were reported. The prognostic ability of quantitative MRI to predict liver-related clinical events has been evaluated in 2 studies. Both studies reported positive correlations, but the CI were wide. Larger cohorts with a longer follow-up time would be useful to further derive the prognostic characteristic of the test. Multiparametric MRI has been used to measure the presence of fibrosis or cirrhosis in the patients who have achieved biochemical remission after treatment in small prospective studies. The evidence is insufficient to determine that the technology results in an improvement in the net health outcome.

For individuals who have chronic liver disease who receive noninvasive radiologic methods other than transient elastography for liver fibrosis measurement, the evidence includes systematic reviews of observational studies. Relevant outcomes are test validity, morbid events, and treatment-related morbidity. Other radiologic methods (e.g., MRE, RTE, ARFI imaging) may have similar performance for detecting significant fibrosis or cirrhosis. Studies have frequently included varying cutoffs not
prespecified or validated. Given these limitations and the imperfect reference standard, it is difficult to interpret performance characteristics. There is no direct evidence that other noninvasive radiologic methods improve health outcomes; further, it is not possible to construct a chain of evidence for clinical utility due to the lack of sufficient evidence on clinical validity. The evidence is insufficient to determine that the technology results in an improvement in the net health outcome.

Supplemental Information
The purpose of the following information is to provide reference material. Inclusion does not imply endorsement or alignment with the evidence review conclusions.

Clinical Input From Physician Specialty Societies and Academic Medical Centers
While the various physician specialty societies and academic medical centers may collaborate with and make recommendations, input received does not represent an endorsement or position statement by the physician specialty societies or academic medical centers, unless otherwise noted.

2015 Input
In response to requests, input was received from 3 physician specialty societies and 3 academic medical centers while this document was under review in 2015. Most reviewers considered noninvasive techniques for the evaluation and monitoring of chronic liver disease to be investigational, both individually and in combination.

Practice Guidelines and Position Statements
Guidelines or position statements will be considered for inclusion in ‘Supplemental Information’ if they were issued by, or jointly by, a US professional society, an international society with US representation, or National Institute for Health and Care Excellence (NICE). Priority will be given to guidelines that are informed by a systematic review, include strength of evidence ratings, and include a description of management of conflict of interest.

Nonalcoholic Fatty Liver Disease
American Gastroenterological Association et al
In 2018, the practice guidelines on the diagnosis and management of nonalcoholic fatty liver disease (NAFLD), developed by the American Gastroenterological Association (AGA), the American Association for the Study of Liver Diseases, and the American College of Gastroenterology, stated that “NFS [NAFLD fibrosis score] or FIB-4 [Fibrosis-4] index are clinically useful tools for identifying NAFLD patients with a higher likelihood of having bridging fibrosis (stage 3) or cirrhosis (stage 4).” This guideline also cited vibration-controlled transient elastography (VCTE) and magnetic resonance elastography (MRE) as “clinically useful tools for identifying advanced fibrosis in patients with NAFLD.”

A 2022 consensus-based clinical care pathway was published by the AGA on risk stratification and management of NAFLD, including some recommendations regarding the use of non-invasive testing for individuals with chronic liver disease. Among individuals with increased risk of NAFLD or nonalcoholic steatohepatitis (NASH)-related fibrosis (i.e., individuals with type-2 diabetes, ≥2 metabolic risk factors, or an incidental finding of hepatic steatosis or elevated aminotransferases), assessment with a nonproprietary fibrosis scoring system such as FIB-4 is recommended, although aspartate transaminase to platelet ratio index can be used in lieu of FIB-4 scoring. Depending on the fibrosis score, imaging-based testing for liver stiffness may be warranted with transient elastography (FibroScan), although bidimensional shear wave elastography or point shear wave elastography are also imaging options included in the clinical care pathway.

American Association of Clinical Endocrinology and American Association for the Study of Liver Diseases
A 2022 joint clinical practice guideline issued by the American Association of Clinical Endocrinology and American Association for the Study of Liver Diseases included the following recommendations on
the use of noninvasive techniques for diagnosis of NAFLD with clinically significant fibrosis (stage F2 to F4):  

- Clinicians should use liver fibrosis prediction calculations to assess the risk of NAFLD with liver fibrosis. The preferred noninvasive initial test is the FIB-4 (Grade B, Level 2 evidence)  
- High-risk individuals with indeterminate or high FIB-4 score for further workup with an transient elastography or enhanced liver fibrosis test, as available (Grade B, Level 2 evidence)  
- Clinicians should prefer the use of transient elastography as best validated to identify advanced disease and predict liver-related outcomes. Alternative imaging approaches may be considered, including shear wave elastography (less well validated) and/or magnetic resonance elastography (most accurate but with a high cost and limited availability; best if ordered by liver specialist for selected cases) (Grade B, Level 2 evidence).

National Institute for Health and Care Excellence
In 2016, the NICE published guidance on the assessment and management of NAFLD. The guidance did not reference elastography. The guidance recommended the enhanced liver fibrosis test to test for advanced liver fibrosis, utilizing a cutoff enhanced liver fibrosis score of 10.51.

American Gastroenterological Association Institute
In 2017, the American Gastroenterological Association Institute published guidelines on the role of elastography in chronic liver disease. The guidelines indicate that, in adults with NAFLD, VCTE has superior diagnostic sensitivity and specificity for diagnosing cirrhosis when compared to the aspartate aminotransferase platelet ratio index (APRI) or FIB-4 tests (very low quality of evidence). Moreover, the guidelines state that, in adults with NAFLD, magnetic resonance-guided elastography has little or no increased diagnostic accuracy for identifying cirrhosis compared with VCTE in patients who have cirrhosis, and has higher diagnostic accuracy than VCTE in patients who do not have cirrhosis (very low quality of evidence).

Hepatitis B and C Viruses
National Institute for Health and Care Excellence
In 2017, the NICE published updated guidance on the management and treatment of patients with hepatitis B virus. The guidance recommends offering transient elastography as the initial test in adults diagnosed with chronic hepatitis B, to inform the antiviral treatment decision (Table 14).

American Association for the Study of Liver Diseases and Infectious Diseases Society of America
In 2020, the American Association for the Study of Liver Diseases and Infectious Diseases Society of America guidelines for testing, managing, and treating hepatitis C virus (HCV) recommended that, for counseling and pretreatment assessment purposes, the following should be completed:

"Evaluation for advanced fibrosis using noninvasive markers and/or elastography, and rarely liver biopsy, is recommended for all persons with HCV infection to facilitate decision making regarding HCV treatment strategy and determine the need for initiating additional measures for the management of cirrhosis (e.g., hepatocellular carcinoma screening) Rating: Class I, Level A [evidence and/or general agreement; data derived from multiple randomized trials, or meta-analyses]."
The guidelines noted that there are several noninvasive tests to stage the degree of fibrosis in patients with HCV. Tests included indirect serum biomarkers, direct serum biomarkers, and VCTE. The guidelines asserted that no single method is recognized to have high accuracy alone and careful interpretation of these tests is required.

**American Gastroenterological Association Institute**

In 2017, guidelines published by the American College of Gastroenterology Institute on the role of elastography in chronic liver disease indicated that, in adults with chronic hepatitis B virus and chronic HCV, VCTE has superior diagnostic performance for diagnosing cirrhosis when compared to the APRI and FIB-4 tests (moderate quality of evidence for HCV, low quality of evidence for hepatitis B virus). In addition, the guidelines state that, in adults with HCV, magnetic resonance-guided elastography has little or no increased diagnostic accuracy for identifying cirrhosis compared with VCTE in patients who have cirrhosis, and has lower diagnostic accuracy than VCTE in patients who do not have cirrhosis (very low quality of evidence).

**Chronic Liver Disease**

**American College of Radiology**

In 2020, the American College of Radiology appropriateness criteria rated ultrasound shear wave elastography as an 8 (usually appropriate) for the diagnosis of liver fibrosis in patients with chronic liver disease. The criteria noted that high-quality data can be difficult to obtain in obese patients, and assessments of liver stiffness can be confounded by parenchyma, edema, inflammation, and cholestasis.

**U.S. Preventive Services Task Force Recommendations**

A 2020 U.S. Preventive Services Task Force Recommendation Statement for HCV screening notes that a diagnostic evaluation for fibrosis stage or cirrhosis with a noninvasive test reduces the risk for harm compared to a liver biopsy. This statement does not give preference to a specific noninvasive test.

**Medicare National Coverage**

There is no national coverage determination. In the absence of a national coverage determination, coverage decisions are left to the discretion of local Medicare carriers.

**Ongoing and Unpublished Clinical Trials**

Some currently ongoing and unpublished trials that might influence this review are listed in Table 15.

### Definitions of Decision Determinations

**Medically Necessary:** Services that are Medically Necessary include only those which have been established as safe and effective, are furnished under generally accepted professional standards to treat illness, injury or medical condition, and which, as determined by Blue Shield, are: (a) consistent with Blue Shield medical policy; (b) consistent with the symptoms or diagnosis; (c) not furnished primarily for the convenience of the patient, the attending Physician or other provider; (d) furnished at the most appropriate level which can be provided safely and effectively to the patient; and (e) not more costly than an alternative service or sequence of services at least as likely to produce equivalent therapeutic or diagnostic results as to the diagnosis or treatment of the Member’s illness, injury, or disease.

**Investigational/Experimental:** A treatment, procedure, or drug is investigational when it has not been recognized as safe and effective for use in treating the particular condition in accordance with generally accepted professional medical standards. This includes services where approval by the federal or state governmental is required prior to use, but has not yet been granted.

**Split Evaluation:** Blue Shield of California/Blue Shield of California Life & Health Insurance Company (Blue Shield) policy review can result in a split evaluation, where a treatment, procedure, or drug will be considered to be investigational for certain indications or conditions, but will be deemed safe and
effective for other indications or conditions, and therefore potentially medically necessary in those instances.

**Prior Authorization Requirements and Feedback (as applicable to your plan)**

Within five days before the actual date of service, the provider must confirm with Blue Shield that the member’s health plan coverage is still in effect. Blue Shield reserves the right to revoke an authorization prior to services being rendered based on cancellation of the member’s eligibility. Final determination of benefits will be made after review of the claim for limitations or exclusions.

Questions regarding the applicability of this policy should be directed to the Prior Authorization Department at (800) 541-6652, or the Transplant Case Management Department at (800) 637-2066 ext. 3507708 or visit the provider portal at [www.blueshieldca.com/provider](http://www.blueshieldca.com/provider).

We are interested in receiving feedback relative to developing, adopting, and reviewing criteria for medical policy. Any licensed practitioner who is contracted with Blue Shield of California or Blue Shield of California Promise Health Plan is welcome to provide comments, suggestions, or concerns. Our internal policy committees will receive and take your comments into consideration.

For utilization and medical policy feedback, please send comments to: MedPolicy@blueshieldca.com

*Disclaimer: This medical policy is a guide in evaluating the medical necessity of a particular service or treatment. Blue Shield of California may consider published peer-reviewed scientific literature, national guidelines, and local standards of practice in developing its medical policy. Federal and state law, as well as contract language, including definitions and specific contract provisions/exclusions, take precedence over medical policy and must be considered first in determining covered services. Member contracts may differ in their benefits. Blue Shield reserves the right to review and update policies as appropriate.*

Transient elastography (FibroScan) imaging may be considered <em>medically necessary</em> once for the evaluation of <em>patients</em> with chronic liver disease.&lt;br&gt;V. Transient elastography (FibroScan) imaging is considered <em>investigational</em> for monitoring of <em>patients</em> with chronic liver disease.&lt;br&gt;VI. The use of other noninvasive imaging is considered <em>investigational</em> for the evaluation or monitoring of <em>patients</em> with chronic liver disease including but not limited to <em>any</em> of the following:&lt;br&gt;   A. Magnetic resonance elastography&lt;br&gt;   B. Multiparametric magnetic resonance imaging&lt;br&gt;   C. Acoustic radiation force impulse imaging (ARFI; e.g., acuson s2000)&lt;br&gt;   D. Real-time tissue elastography</td>
<td><strong>Policy Statement:</strong>&lt;br&gt;I. A single FibroSURE multianalyte assay may be considered <em>medically necessary</em> once for the evaluation of <em>individuals</em> with chronic liver disease.&lt;br&gt;II. FibroSURE multianalyte assays are considered <em>investigational</em> for monitoring of <em>individuals</em> with chronic liver disease.&lt;br&gt;III. Other multianalyte assays with algorithmic analyses are considered <em>investigational</em> for the evaluation or monitoring of <em>individuals</em> with chronic liver disease.&lt;br&gt;IV. Transient elastography (FibroScan) imaging may be considered <em>medically necessary</em> once for the evaluation of <em>individuals</em> with chronic liver disease.&lt;br&gt;V. Transient elastography (FibroScan) imaging is considered <em>investigational</em> for monitoring of <em>individuals</em> with chronic liver disease.&lt;br&gt;VI. The use of other noninvasive imaging is considered <em>investigational</em> for the evaluation or monitoring of <em>individuals</em> with chronic liver disease including but not limited to <em>any</em> of the following:&lt;br&gt;   A. Magnetic resonance elastography&lt;br&gt;   B. Multiparametric magnetic resonance imaging&lt;br&gt;   C. Acoustic radiation force impulse imaging (ARFI; e.g., acuson s2000)&lt;br&gt;   D. Real-time tissue elastography</td>
