2.04.140 Proteogenomic Testing for Patients with Cancer (GPS Cancer™ Test)

Original Policy Date: September 1, 2016  Effective Date: August 1, 2017
Section: 2.0 Medicine  Page: Page 1 of 13

Policy Statement

Proteogenomic testing (see Policy Guidelines section) of patients with cancer (including, but not limited to the GPS Cancer™ test) is considered investigational for all indications.

Policy Guidelines

Proteogenomic testing involves the integration of proteomic, transcriptomic, and genomic information. Proteogenomic testing can be differentiated from proteomic testing, in that proteomic testing can refer to the measurement of protein products alone, without integration of genomic and transcriptomic information. When protein products alone are tested, this is not considered proteogenomic testing.

Genetics Nomenclature Update

Human Genome Variation Society (HGVS) nomenclature is used to report information on variants found in DNA and serves as an international standard in DNA diagnostics. It is being implemented for genetic testing medical evidence review updates starting in 2017 (see Table PG1). HGVS nomenclature is recommended by HGVS, the Human Variome Project, and the Human Genome Organization (HUGO).

The American College of Medical Genetics and Genomics (ACMG) and Association for Molecular Pathology (AMP) standards and guidelines for interpretation of sequence variants represent expert opinion from ACMG, AMP, and the College of American Pathologists. These recommendations primarily apply to genetic tests used in clinical laboratories, including genotyping, single genes, panels, exomes, and genomes. Table PG2 shows the recommended standard terminology—“pathogenic,” “likely pathogenic,” “uncertain significance,” “likely benign,” and “benign”—to describe variants identified that cause Mendelian disorders.

Genetic Counseling

Genetic counseling is primarily aimed at patients who are at risk for inherited disorders, and experts recommend formal genetic counseling in most cases when genetic testing for an inherited condition is considered. The interpretation of the results of genetic tests and the understanding of risk factors can be very difficult and complex. Therefore, genetic counseling will assist individuals in understanding the possible benefits and harms of genetic testing, including the possible impact of the information on the individual’s family. Genetic counseling may alter the utilization of genetic testing substantially and may reduce inappropriate testing.
Genetic counseling should be performed by an individual with experience and expertise in genetic medicine and genetic testing methods.

**Coding**
There is no specific CPT code for the GPS Cancer test. It would likely be reported with the unlisted molecular pathology procedure code 81479.

### Description
Proteogenomics refers to the integration of genomic data with proteomic and transcriptomic data to provide a more complete picture of the function of the genome. The current focus of proteogenomics is primarily on the diagnostic, prognostic, and predictive potential of proteogenomics in various cancers. There is one commercially available proteogenomic test, the GPS Cancer test.

### Related Policies
- N/A

### Benefit Application
Benefit determinations should be based in all cases on the applicable contract language. To the extent there are any conflicts between these guidelines and the contract language, the contract language will control. Please refer to the member's contract benefits in effect at the time of service to determine coverage or non-coverage of these services as it applies to an individual member.

Some state or federal mandates [e.g., Federal Employee Program (FEP)] prohibits plans from denying Food and Drug Administration (FDA)-approved technologies as investigational. In these instances, plans may have to consider the coverage eligibility of FDA-approved technologies on the basis of medical necessity alone.

### Regulatory Status
Clinical laboratories may develop and validate tests in-house and market them as a laboratory service; laboratory-developed tests must meet the general regulatory standards of the Clinical Laboratory Improvement Act. The GPS Cancer™ test (NantHealth, Culver City, CA) is available under the auspices of Clinical Laboratory Improvement Amendments. Laboratories that offer laboratory-developed tests must be licensed by Clinical Laboratory Improvement Amendments for high-complexity testing. To date, the U.S. Food and Drug Administration has chosen not to require any regulatory review of this test.

### Rationale
**Background**
This evidence review provides an overview of the emerging field of proteogenomics, with an emphasis on the currently available proteogenomic test, GPS Cancer test. In addition to focusing on the GPS Cancer test, this review describes and outlines types of proteogenomic research currently reported in the literature and that have potential clinical applications.

**Proteogenomics**
The term proteome refers to the entire complement of proteins produced by an organism or cellular system, and proteomics refers to the large-scale comprehensive study of a specific proteome. Similarly, the term transcriptome refers to the entire complement of transcription products (messenger RNAs [mRNAs]), and transcriptomics refers to the study of a specific
transcriptome. Proteogenomics refers to the integration of genomic information with proteomic and transcriptomic information to provide a more complete picture of the function of the genome.

A system’s proteome is related to its genome and genomic alterations. However, while the genome is relatively static over time, the proteome is more dynamic and may vary over time and/or in response to selected stressors. Proteins undergo a number of modifications as part of normal physiologic processes. Following protein translation, modifications occur by splicing events, alternative folding mechanisms, and incorporation into larger complexes and signaling networks. These modifications are linked to protein function and result in functional differences that occur by location and over time.

Some of the main potential applications of proteogenomics in medicine include:
- Identifying biomarkers for diagnostic, prognostic, and predictive purposes
- Detecting cancer by proteomic profiles or “signatures”
- Quantitating levels of proteins and monitoring levels over time for:
  - Cancer activity
  - Early identification of resistance to targeted tumor therapy
- Correlating protein profiles with disease states

Proteogenomics is an extremely complex field due to the intricacies of protein architecture and function, the many potential proteomic targets that can be measured, and the numerous testing methods used. We discuss the types of targets currently being investigated and the testing methods used and under development next.

**Proteomic Targets**
A proteomic target can be any altered protein that results from a genetic variant. Protein alterations can result from both germline and somatic genetic variants. Altered protein products include mutated proteins, fusion proteins, alternative splice variants, noncoding mRNAs, and posttranslational modifications (PTMs).

**Sequence Alterations (Mutated Protein)**
A mutated protein has an altered amino acid sequence that arises from a genetic variant. A single amino acid may be replaced in a protein or multiple amino acids in sequence may be affected. Mutated proteins can arise from either germline or somatic genetic variants. Somatic variants can be differentiated from germline variants by comparison with normal and disease tissue.

**Fusion Proteins**
Fusion proteins are the product of one or more genes that fuse together. Most fusion genes discovered to date have been oncogenic, and fusion genes have been shown to have clinical relevance in a variety of cancers.

**Alternative Splice Events**
Posttranslational enzymatic splicing of proteins results in numerous protein isoforms. Alternative splicing events can lead to abnormal protein isoforms with altered function. Some alternative splicing events have been associated with tumor-specific variants.

**Noncoding RNAs**
Noncoding portions of the genome serve as the template for noncoding RNA (ncRNA), which plays various roles in the regulation of gene expression. There are 2 classes of ncRNA: shorter ncRNAs, which include microRNAs and related transcript products, and longer ncRNAs, which are thought to be involved in cancer progression.
Posttranslational Modifications

PTMs of histone proteins occur in normal cells and are genetically regulated. Histone proteins are found in the nuclei and play a role in gene regulation by structuring the DNA into nucleosomes. A nucleosome is composed of a histone protein core surrounded by DNA. Nucleosomes are assembled into chromatin fibers composed of multiple nucleosomes assembled in a specific pattern. PTMs of histone proteins include a variety of mechanisms, including methylation, acetylation, phosphorylation, glycosylation, and related modifications.

Proteogenomic Testing Methods

Proteogenomic testing involves isolating, separating, and characterizing proteins from biologic samples, followed by correlation with genomic and transcriptomic data. Isolation of proteins is accomplished by tryptic digestion and solubilization. The soluble mix of protein isolates is then separated into individual proteins. This is generally done in multiple stages using high-performance liquid chromatography ion-exchange chromatography, 2-dimensional gel electrophoresis, and related methods. Once individual proteins are obtained, they may be characterized using various methods and parameters, some of which we describe below.

Immunohistochemistry/Fluorescence in situ Hybridization

Immunohistochemistry (IHC) and fluorescence in situ hybridization are standard techniques for isolating and characterizing proteins. IHC identifies proteins by using specific antibodies that bind to the protein. Therefore, this technique can only be used for known proteins and protein variants because it relies on the availability of a specific antibody. This technique also can only test a relatively small number of samples at once.

There are a number of reasons why IHC and fluorescence in situ hybridization are not well-suited for large-scale proteomic research. They are semiquantitative techniques and involve subjective interpretation. They are considered low-throughput assays that are time-consuming and expensive and require a relatively large tissue sample. Some advances in IHC and fluorescence in situ hybridization have addressed these limitations, including tissue microarray and reverse phase protein array.

• Tissue microarrays can be constructed that enable simultaneous analysis of up to 1000 tissue samples.
• Reverse phase protein array, a variation on tissue microarrays, allows for a large number of proteins to be quantitated simultaneously.

Mass Spectrometry

Mass spectrometry (MS) separates molecules by their mass to charge ratio and has been used as a research tool for studying proteins for many years. Development of technology that led to the application of MS to biologic samples has advanced the field of proteogenomics rapidly. However, the application of MS to clinical medicine is in its formative stages. There are currently several types of mass spectrometers and a lack of standardization in the testing methods. Additionally, MS equipment is expensive and currently largely restricted to tertiary research centers.

The potential utility of MS lies in its ability to provide a wide range of proteomic information in an efficient manner, including:

• Identification of altered proteins;
• Delineation of protein or peptide profiles for a given tissue sample;
• Amino acid sequencing of proteins or peptides;
• Quantitation of protein levels;
• 3-dimensional protein structure and architecture; and
• Identification of PTMs.

“Top-down” MS refers to identification and characterization of all proteins in a sample without prior knowledge of which proteins are present. This method provides a profile of all proteins in a system, including documentation of PTMs and other protein isoforms. This method, therefore,
provides a protein “profile” or “map” of a specific system. Following initial analysis, intact proteins can be isolated and further analyzed to determine amino acid sequences and related information.

“Bottom-up” MS refers to the identification of known proteins in a sample. This method identifies peptide fragments that indicate the presence of a specific protein. This method depends on having peptide fragments that can reliably identify a specific protein. Selective reaction monitoring-MS is a bottom-up modification of MS that allows for direct quantification and specific identification of low-abundance proteins without the need for specific antibodies. This method requires the selection of a peptide fragment or “signature” that is used to target the specific protein. Multiplex assays have also been developed to quantitate the epidermal growth factor receptor, human epidermal growth factor receptors 2 and 3, and insulin-like growth factor-1 receptor.

Bioinformatics
Due to the complexity of proteomic information, the multiple tests used, and the need to integrate this information with other genomic data, a bioinformatics approach is necessary to interpret proteogenomic data. Software programs are available that integrate and assist in the interpretation of the vast amounts of data generated by proteogenomics research. One software platform that integrates genomic and proteomic information is PARADIGM, which is used by The Cancer Genome Atlas (TCGA) project for data analysis. Other software tools currently available include:

- The Genome Peptide Finder matches the amino acid sequence of peptides predicted de novo with the genome sequence.
- The Proteogenomic Mapping Tool is an academic software for mapping peptides to the genome.
- Peppy is an automated search tool that generates proteogenomic data from translated databases and integrates this information for analysis.
- VESPA is a software tool that integrates data from various platforms and provides a visual display of integrated data.

Ongoing Proteogenomic Database Projects
Numerous ongoing databases are being constructed for proteogenomic research. Some are shown in Table 1.

**GPS Cancer Test**
The GPS Cancer test is a commercially available proteogenomic test intended for patients with cancer. The test includes whole-genome sequencing (20,000 genes, 3 billion base pairs), whole transcriptome (RNA) sequencing, and quantitative proteomics by mass spectrometry. The test is intended to inform personalized treatment decisions for cancer, and treatment options are listed when available, although treatment recommendations are not made. Treatment options may include U.S. Food and Drug Administration–approved targeted drugs with potential for clinical benefit, active clinical trials of drugs with potential for clinical benefit, and/or available drugs to which the cancer may be resistant.

**Literature Review**
The evaluation of a genetic test focuses on 3 main principles: (1) analytic validity (technical accuracy of the test in detecting a variant that is present or in excluding a variant that is absent); (2) clinical validity (diagnostic performance of the test [sensitivity, specificity, positive and negative predictive values] in detecting clinical disease); and (3) clinical utility (i.e., a demonstration that the diagnostic information can be used to improve patient health outcomes).

**Proteogenomic Testing**
**Clinical Context and Test Purpose**
The purpose of proteogenomic testing in patients who have cancer is to detect cancer, improve evaluation of prognosis, select treatments, and monitor for treatment response or resistance.

The question addressed in this evidence review is: Does proteogenomic testing using the GPS Cancer test improve the net health outcome in individuals with cancer?

The following PICOTS were used to select literature to inform this review.

**Patients**
The relevant population of interest is patients with cancer who have indications for genetic testing.
Interventions
The GPS Cancer test is a commercially available proteogenomic test for patients with cancer.

Comparators
Standard clinical workup and genetic testing are used for cancer diagnosis, prognosis, and for monitoring response. Genetic testing using companion diagnostic tests for targeted therapies are generally used to select cancer treatments when targeted therapies are available.

Outcomes
The primary outcomes of interest are overall survival and disease-specific survival. The harmful outcomes resulting from a false test result are outcomes of incorrect or unnecessary treatment and outcomes of incorrect or unnecessary additional testing.

Time
The relevant duration of follow-up for survival outcomes varies by cancer type.

Setting
Decisions about cancer treatment are usually made in the oncology setting.

Analytic Validity
No published literature was identified on the analytic validity of the GPS Cancer test. Additionally, search of selected websites did not identify any data on analytic validity of the test.

Some general studies on the analytic validity of proteogenomics were identified. This literature includes the following types of studies that correlate results of different testing methods.

Catenacci et al (2014) published 2 studies that compared the performance of mass spectrometry (MS) with immunohistochemistry (IHC) and fluorescence in situ hybridization (FISH). In the first study, these 3 methods were used to quantitate the Met protein (hepatocyte growth factor receptor). Overexpression of Met is associated with poor outcomes for a variety of gastrointestinal cancers, and Met levels are currently quantitated by IHC or FISH. This study described development of a selective reaction monitoring-MS (SRM-MS) assay for Met by selecting the optimal peptide sequence and setting technical aspects of the assay. The reliability and reproducibility of the assay were both reported to be high. Results of the SRM-MS assay were then compared with standard IHC and FISH in 130 tissue samples of gastroesophageal cancer, comprised of primary tumor resections, endoscopic primary tumor biopsies, and core needle biopsies of metastatic sites. Forty-four tissue samples had results for both SRM-MS and IHC; the correlation coefficient between these tests was 0.54. Thirty-one tissue samples had results for both SRM-MS and FISH; the correlation coefficient between these tests was 0.89.

In the second study, similar methods were used to quantitate human epidermal growth factor receptor 2 (HER2) levels in 139 tissue samples from gastrointestinal cancers. Reliability and reproducibility of the assay were high. Forty-two tissue samples had both SRM-MS and FISH results; the univariate correlation between the 2 tests was 0.36. When a multivariate model was used to control for expression of the Met protein, epidermal growth factor receptor, and HER3, the correlation between the 2 tests improved to 0.73. One hundred twenty-two samples had results for both SRM-MS and IHC; the correlation between tests was 0.04. Compared with SRM-MS as the criterion standard, IHC was sensitive (89.9%) but not specific (15.2%) in identifying samples with elevated HER2 levels.

Section Summary: Analytic Validity
There is no published evidence on the analytic validity of the GPS Cancer test and, therefore, the analytic validity of this test is undefined. For proteomic research in general, a few types of studies have provided information on analytic validity. The most common type is correlation between SRM-MS results and IHC and/or FISH results. These early studies involved assay
development as well as assay validation, so it is not possible to compare results across different studies. These studies also lacked a true criterion standard to compare SRM-MS with IHC or FISH. Further research is needed to standardize and validate proteogenomic testing adequately for clinical use.

Clinical Validity
No published literature was identified on the clinical validity of the GPS Cancer test. In addition, searches of selected websites did not identify any data on clinical validity of the test. The general published literature on the clinical validity of proteogenomics includes the following types of studies: proteomic biomarkers as prognostic markers, molecular characterization, and monitoring quantitative protein levels.

Proteomic Biomarkers as Prognostic Markers
Some research has compared the association of proteogenomic results with clinical outcomes and compared the strength of association between genomic and proteomic data. Yau et al (2015) published a report comparing whether proteogenomic and genomic data can predict metastatic outcomes in breast cancer.32 This study measured FOXM transcript mRNA levels and compared the prognostic ability with FOXM1 target genes and a gene proliferation score. Table 2 shows the results obtained for each test.

</table>

CI: confidence interval; ER: estrogen receptor; mRNA: messenger RNA.

Zhang et al (2016) combined MS-based proteomic measurements with genomic data of 174 ovarian tumors previously analyzed by TCGA.33 Copy number alterations having high correlation with protein abundance or mRNA were found on chromosomes 2, 7, 20, and 22. A lasso-based Cox proportional hazards model was used to model the association between these copy-number alterations and overall survival on a training set of 82 tumors and then used to predict survival in 87 nonoverlapping tumors. A consensus of the 4 signatures was created, using a voting method, as a binary indicator for signature relative level up versus down. The consensus indicator was highly associated with survival (hazard ratio not given; p<0.001). Comparison to genomic stratification was not given.

Defining Molecular Subtypes of Cancer
Comprehensive molecular characterization has been performed for various cancer types, and in some cases, these investigations have defined subtypes that differ from the standard histologic classification. Clinical validity can be demonstrated in this situation if the molecular subtypes are more homogeneous than the histologic class and correlate more closely with clinical outcomes.

An example of molecular subtyping of cancer by proteogenomics was published by TCGA network in 2015.14 This study integrated data from multiple platforms, including exome sequencing, DNA copy-number profiling, DNA methylation, and protein profiling by MS. For each platform, clusters of similar cases were identified. Three distinct molecular subtypes were identified using a second-level cluster analysis. They were most concordant with isocitrate dehydrogenase enzyme, 1p/19q, and TP53 genetic variant status. The molecular subtypes showed differences in clinical characteristics, recurrence, and survival that could not be explained by histologic class.

Monitoring Quantitative Protein Levels over Time
Quantification of protein levels over time may have applications for determining resistance to targeted therapy. Levels of protein markers may correlate with the presence of resistant tumor
cells and may be an early marker of resistance that occurs before tumor progression. Clinical validity can be demonstrated if quantitative protein levels identify resistance more accurately or earlier than other surveillance methods.

Currently, few studies have reported on monitoring protein levels over time. A case report, published in 2016, demonstrated that repeat quantitation of the HER2, HER3, and epidermal growth factor receptor proteins was feasible and that protein levels changed in response to different therapies and over time.34

**Section Summary: Clinical Validity**
There is no published evidence on the clinical validity of the GPS Cancer test and, therefore, the clinical validity of this test is undefined. For proteomic research in general, a few types of studies in the literature provide information on clinical validity. A small number of studies use proteomic biomarkers for diagnosis or prognosis and compare these biomarkers with traditional genomic testing. Other studies have performed comprehensive molecular characterization of different tumors and, in some cases, have shown that molecular characterization correlates more strongly with clinical outcomes than with histologic classification. The third type of study in the literature quantitates and monitors protein markers over time for surveillance purposes, particularly for the emergence of resistance to targeted cancer therapies. This available research on clinical validity outlines some types of research that will be needed to establish clinical validity for a variety of clinical situations. However, the research is currently in its early stages, and no conclusions on clinical validity can be drawn at present from the evidence.

**Clinical Utility**
No direct evidence on clinical utility was identified. Therefore, the clinical utility of the GPS Cancer test is uncertain. For proteomic testing in general, there is no published literature on clinical utility. Furthermore, absent additional evidence establishing the analytic and clinical validity of proteomic testing, it will not be possible to determine whether clinical utility is present.

**Summary of Evidence**
For individuals who have cancer and indications for genetic testing who receive proteogenomic testing (GPS Cancer test), the evidence includes cross-sectional studies that correlate results with standard testing and that report comprehensive molecular characterization of various cancers, and cohort studies that use proteogenomic markers to predict outcomes and that follow quantitative levels over time. Relevant outcomes are overall survival, disease-specific survival, test accuracy and validity, and treatment-related mortality and morbidity. There is no published evidence on the analytic validity or clinical utility of the GPS Cancer test. For proteogenomic testing in general, the research is at an early stage. There is a lack of standardization of testing methods and uncertain accuracy for most proteogenomic technologies. A few studies have described assay development and validation for proteogenomic targets and correlation of proteogenomic testing results with standard testing methods. Other studies have used proteogenomic in conjunction with genomic testing to provide a more comprehensive molecular characterization of various cancers. Very few studies have used proteogenomic tumor markers for diagnosis or prognosis, and at least 1 study has reported following quantitative protein levels for surveillance purposes. Further research is needed to standardize and validate proteogenomic testing methods. When standardized and validated testing methods are available, the analytic validity and clinical utility of proteogenomic testing can be adequately evaluated. The evidence is insufficient to determine the effect of the technology on health outcomes.

**Supplemental Information**
**Practice Guidelines and Position Statements**
No guidelines or statements were identified.
U.S. Preventive Services Task Force Recommendations

Not applicable.

Medicare National Coverage

There is no national coverage determination. In the absence of a national coverage determination, coverage decisions are left to the discretion of local Medicare carriers.

Ongoing and Unpublished Clinical Trials

Some currently unpublished trials that might influence this review are listed in Table 3.

**Definitions of Decision Determinations**

**Medically Necessary:** A treatment, procedure, or drug is medically necessary only when it has been established as safe and effective for the particular symptoms or diagnosis, is not investigational or experimental, is not being provided primarily for the convenience of the patient or the provider, and is provided at the most appropriate level to treat the condition.

**Investigational/Experimental:** A treatment, procedure, or drug is investigational when it has not been recognized as safe and effective for use in treating the particular condition in accordance with generally accepted professional medical standards. This includes services where approval by the federal or state governmental is required prior to use, but has not yet been granted.

**Split Evaluation:** Blue Shield of California/Blue Shield of California Life & Health Insurance Company (Blue Shield) policy review can result in a split evaluation, where a treatment, procedure, or drug will be considered to be investigational for certain indications or conditions, but will be deemed safe and effective for other indications or conditions, and therefore potentially medically necessary in those instances.

**Prior Authorization Requirements (as applicable to your plan)**

Within five days before the actual date of service, the provider must confirm with Blue Shield that the member's health plan coverage is still in effect. Blue Shield reserves the right to revoke an authorization prior to services being rendered based on cancellation of the member's eligibility. Final determination of benefits will be made after review of the claim for limitations or exclusions.
Questions regarding the applicability of this policy should be directed to the Prior Authorization Department. Please call (800) 541-6652 or visit the provider portal at www.blueshieldca.com/provider.

Disclaimer: This medical policy is a guide in evaluating the medical necessity of a particular service or treatment. Blue Shield of California may consider published peer-reviewed scientific literature, national guidelines, and local standards of practice in developing its medical policy. Federal and state law, as well as contract language, including definitions and specific contract provisions/exclusions, take precedence over medical policy and must be considered first in determining covered services. Member contracts may differ in their benefits. Blue Shield reserves the right to review and update policies as appropriate.
